# Introduction

Thank you for choosing **ScriptEase**!

**ScriptEase** is a high-performance implementation of JavaScript, highly customizable and portable to a wide variety of operating systems. No matter your scripting needs, ScriptEase has you covered.

In this manual we show you how to add scripting support via **ScriptEase** to your application, use the extensive **ScriptEase API** to control your scripting, and perform a large number of common scripting tasks. This manual does not replace the **ScriptEase** Language Reference. Refer to that guide for information on JavaScript and **ScriptEase** extensions to it.

Let's dive right in by looking at integrating **ScriptEase** into your application.

# Integration Into Your C/C++ Application

This chapter contains the instructions you'll need to integrate the ScriptEase ISDK into your C/C++ application. This step involves setting up your project and linking with the ScriptEase libraries. The rest of this manual builds on this chapter, showing you how to use the ScriptEase API to script your application.

---

## Integration on Windows Systems

Integrating ScriptEase ISDK into your application consists of the following basic steps.

**Note:** If you are using Microsoft Visual Studio as your development environment, we recommend you check out the *Getting Started* section of the ScriptEase ISDK Toolbox. It gives you a step-by-step approach to integration into a Visual Studio project.

### Configuring A jseopt.h File

ScriptEase ISDK uses a header file called `jseopt.h` that specifies the compiler options that should be turned off/on when ScriptEase libraries are built. All ScriptEase ISDK applications need a `jseopt.h` file to specify the various options that are desired for that particular application.

New with Version 5.0, you can use the [Selib Assistant](#) to configure the `jseopt.h` file.

### Build ScriptEase Libraries

In order to incorporate the changes you made to the `jseopt.h` file, you must rebuild the ScriptEase object module libraries. These libraries contain the ScriptEase code you will link with your application in a later step.

If you are using Visual Studio, use Selib Assistant's Build Libraries mode to build the ScriptEase ISDK's libraries.

### Link ScriptEase Library Files

Your next step is to link the newly created ScriptEase object module libraries with your application.

For Visual Studio projects, Selib Assistant can automatically add these files to your `.dsp` file and optionally add the ScriptEase `.dsp` files to your Workspace (`.dsw` file).

---

## Integration on Unix Systems

### Unpacking ScriptEase:ISDK/C

The distribution you received should first be installed on your system. For Unix, the distribution is a compressed tar files that can be unpacked anywhere on your system. This unpacking will produce a single directory tree containing the ScriptEase ISDK installation. This tree contains all of the files you will need to integrate the ScriptEase ISDK into your application. It also contains a number of sample ISDK applications. In this manual, we will often refer to filenames and directories. Those should be understood to be relative to the directory you unpacked ScriptEase into. For instance, if you unpacked ScriptEase in the directory `/usr/src/se501` and we refer to the filename `src/include/foo.h`, then you should understand that to be referring to the file `/usr/src/se501/src/include/foo.h` on your system.

The ScriptEase distribution contains a number of subdirectories. The `lib` directory contains the makefiles and targets to build the ScriptEase ISDK library files themselves. If you have received an evaluation version, prebuilt versions to link with are in this directory. The `src` directory contains the ScriptEase source code. The `manual` directory contains a copy of the manual. The `tests` directory contains script tests for the engine. The `tools` directory contains some scripts for ScriptEase self-testing. Finally, the `samples` directory contains some simple applications that use the ScriptEase ISDK.

## Sample Applications

Before integrating the **ScriptEase ISDK** into your own application, it is suggested you compile and run some of the sample applications provided with the distribution. They are found in the `samples` directory. The samples `sample0` and `sample1` are basic samples that are most appropriate to learn from.

For Unix distributions, the samples can be built from the root of the distribution using the supplied makefile. To do so, type the command `make <sample name>`. For instance, to build the `sample1` sample you would type the command:

```
make sample1
```

Once built, the sample executable can be found in a subdirectory corresponding to the system name. For example, the `sample1` executable built with the above command built on Linux can be found as `samples/sample1/linux/sample1`.

While each unix ScriptEase distribution will use the appropriate defines, there are some systems that have multiple define packages corresponding to different compilers on that system. All systems will by default build using `gcc`. You can specify an alternative define package in any invocation of `make` on a ScriptEase makefile by specifying the `SYSTEM_NAME` in the invocation. For example, to use the Sun Forte C compiler on a Solaris system to build the `sample1` sample, you would use:

```
make SYSTEM_NAME=solarisc sample1
```

The following table lists all valid system names:

System	Make text to use
-----	-----

Aix	aix
Digital Unix	dec
FreeBSD	freebsd
HP-UX	hpux
Linux	linux
Irix	irix
Solaris	solaris, solarisc

\*The `solaris` build is for using `gcc` on Solaris. The `solarisc` version is for using Sun's Forte C compiler.

## Integration Basics

Integrating the ScriptEase ISDK with your application requires a few basic tasks as outlined below. Make sure to complete each task.

### Edit your `jseopt.h`

The first step is to edit the `lib/jseopt.h` file found in the distribution. This file is self-documenting by its comments. Each compiler switch or option has a description of what altering it will do. Change all switch or option to your preference.

### Rebuild the ScriptEase libraries

In order to incorporate the changes you made to the `lib/jseopt.h` file, you must rebuild the ScriptEase object module libraries. These libraries contain the ScriptEase code you will link with your application in a later step.

For Unix, you build these libraries from the root of the ScriptEase distribution just like you built the samples above. Instead of using the name of the a sample, use the name `core`.

### Add ScriptEase compiler options

The next step is to alter your application's compiler settings to correctly work with ScriptEase. The only option required is to set your compiler's include paths so it can find the ScriptEase header files as well as the `lib/jseopt.h` file. If you move your `lib/jseopt.h` file to an alternate location, you must include its directory in your include path, before any other ScriptEase directories. Then include the following directories. Recall, all directories are relative to the directory you installed ScriptEase in:

```
lib
.
src/misc
src/lib
src/app
src/include
```

Each compiler has some way to specify additional include directories to search for include files. When using a graphical IDE, you will find a field to put additional directories in. When using a command line version, a particular

command-line switch will add them, usually `-I`. Please consult your compiler's documentation if you are unsure how to add include directories to your project.

### **Program your application to invoke ScriptEase**

This topic is subject of the rest of the manual. Here we will only mention that all of your source files that are to invoke ScriptEase must have the following line:

```
#include "jseopt.h"
```

### **Link with the ScriptEase libraries**

The final step for integrating your application with ScriptEase is to link the ScriptEase object module libraries with your application. There are two object module libraries to link. These libraries are found within the `lib/core` and `lib/library` directory trees. The particular directory is identical to the text string associated with your operating system, as described above. Within those directories are `user` subdirectories, where your version of the ScriptEase libraries was placed when built in an earlier step. The libraries are named `libsec501ar.a` and `libsel501ar.a` respectively. For instance, if your system is AIX, then you would link with the object module libraries named `lib/core/aix/user/libsec501ar.a` and `lib/library/aix/user/libsel501ar.a`.

In addition to the release versions of the libraries, debugging versions are produced with the full version of ScriptEase. The library names end with an `r` for a release version and a `d` for a debug version. The AIX debug libraries are named `lib/core/aix/user/libsec501ad.a` and `lib/library/aix/user/libsel501ad.a`.

### **Using an alternate jseopt.h**

Some users may require multiple `jseopt.h` files for multiple ScriptEase configurations. To accomplish this, first copy your `lib/jseopt.h` file to a new directory. Second, decide on an alternate directory name within the `lib` directory to have the ScriptEase object modules produced instead of the default `user`. For instance, you may want to use the name `myconfig1`. In this case, instead of finding the the AIX files in `lib/core/aix/user`, you would find them in `lib/core/aix/myconfig1`.

To rebuild a particular version of the ScriptEase libraries, you need to supply this information in the `make` command that builds them. Provide the variable `JSEOPT_DIR` with the full path of the directory you put the `jseopt.h` file in. Provide the variable `BUILD_SUBDIR` with the name of the subdirectory for your build. For instance, you might use:

```
make JSEOPT_DIR=/usr/src/myconfig1 BUILD_SUBDIR=myconfig1 aix-  
core
```

You will need to link your application with the particular version of the ScriptEase library you have just built.

---

## **Advanced Integration - Debugging**

A debug mode build is differentiated by the presence or absence of the `NDEBUG` flag. When this flag is on, asserts are removed and the fastest code is generated

while when it is off, asserts are fleshed out to catch errors. ScriptEase follows this convention. When `NDEBUG` is undefined, ScriptEase adds a lot of debugging code. ScriptEase builds debug and non-debug versions of its core and places them in specific directories as described above.

Using the debug build, many of the common ScriptEase problems, both in integration and scripting, are detected and reported to you. We encourage you to develop your application using the debug-mode of the ScriptEase library before contacting Nombas for technical support. Carefully following this manual chapter and building a debug-mode version will eliminate 90% of the problems commonly encountered and will save you valuable time rather than waiting for technical support to get to your question. If you encounter a true bug in our core, the added information produced in the debug-mode build will allow us to find it and create an errata more quickly.

Before you proceed to the next chapter on scripting your application, please look over the following common problems you will encounter. It is best to keep these in mind first, as many good habits are introduced. If you think of catching bugs as something to be done after your code is written, you will unfortunately spend a lot more time catching them. Prevention is the best cure.

## Jsedebug.Log

This is the name of the debug output file. Under DOS, Windows, or OS/2, this file is created in the root of `c:\`. For UNIX and Mac versions, it is put in the current directory. The debug output will be put in this file, appended to whatever the file already contains. When trying to debug your program, delete this file first, run your program, then read the file to see what information it provides. Even if this information is not enough for you to fix the problem, it will be helpful to us, so include it when you contact Nombas for technical support.

## Memory Tracking

The second main benefit of the ScriptEase ISDK debug code is that it internally tracks all memory allocated. When memory is allocated or freed, it is filled with garbage values so memory that is freed but later accessed will contain garbage and thus be likely to cause an immediate problem. If your program crashes, look at the data structure involved. If it is working with a dynamically-allocated memory and has the hex value `0xEE` (for instance, the pointer `0xEEEEEEEE`), it is likely an uninitialized value, since all allocated memory is filled with this value. If you instead find `0xBD` (or `0xBDBDBDBD` as a pointer), you are using memory that has since been freed. Of course, you'll then need to track down why you are using bad memory, but at least you know that you are.

Second, on exit, all memory is examined, and if some memory was not freed, it will be reported (in the `jsedebug.log` file, described above.) Special markers are written before and after each memory block, so if you have gone outside the bounds of the allocated memory, this too will be caught. These reports tell you the file name and line number that the memory was allocated on.

Occasionally, there will be a crash in these routines themselves. If the function crashing is in `src/misc/jsemem.c`, this is such a case. This happens when the internal lists have become corrupted. The most common cause is writing past the bounds of an allocation. While we buffer allocations with a few bytes on either

end, sometimes a runaway program will write well beyond these safety margins and lead to this problem.

You can have memory allocated by your program included in this memory tracking code by using the ScriptEase memory allocation routines. Here are the prototypes for these functions. They function similarly to their C standard library counterparts except each takes an `secontext` as a parameter and will perform garbage collection if not enough memory is available. Each returns `NULL` if the requested memory could not be allocated even after collecting. In this case, a memory allocation failure error object is also set as the `SE_RETURN, SE_VALUE` member pair and the error flag is turned on. If you are in a wrapper function when this happens, you can immediately return from it and have the memory failure error be the return of your wrapper function.

```
void *seGCMalloc(secontext se, size_t size);
void *seGCRealloc(secontext se, void *orig, size_t newsize);
secharptr seGCStrdup(secontext se, seconstcharptr orig);
secharptr seGCStrndup(secontext se, seconstcharptr orig, size_t
len);
void seGCFree(secontext se, void *item);
```

## Jsememreport

Although pointer-bounds problems will be caught on exit, many times this mistake will cause the program to crash long before exit. If you suspect the problem may be due to memory corruption, put this line in your code before the crash:

```
jseMemReport(False);
```

Try to make it as close to the crash as possible. This causes all of the bounds checks described above to be made so it is a very slow call, too slow to call frequently even in a debug build. However, if memory has been corrupted, this call will usually find it. It is another good tool to help find memory corruption problems.

# ScriptEase Types

ScriptEase is designed to be portable to a wide variety of systems such as Windows, Mac, various Unix flavors, and others. Similarly, it is designed to handle ASCII, UNICODE, and MBCS builds. In order to do so, ScriptEase uses a number of types and macros to ensure portability. This chapter goes through all the special ScriptEase datatypes and their use.

The following types are defined via typedefs for use in ScriptEase programs:

---

## secontext

A handle to a ScriptEase scripting context. Every ScriptEase function except for the initialization functions takes an `secontext` as its first parameter.

---

## sedatatype

Represents the possible datatypes a ScriptEase variable can have. The following are the possible values for a variable of type `sedatatype`:

- `SE_UNDEFINED`

The value is the undefined value which is a particular value in JavaScript. The JavaScript expression `void 0` generates an undefined value. Variables created with the `var` statement but not yet assigned any value likewise are of the undefined value.

- `SE_NULL`

The value is the JavaScript `null` value.

- `SE_BOOL`

The value is a boolean, either `true` or `false`, and maps to the ScriptEase C `sebool` typedef described below.

- `SE_NUMBER`

ScriptEase can be built with floating point enabled or disabled. If it is disabled, ScriptEase numbers are integers only, otherwise they are floating point number. The ScriptEase typedef `senumber` is used to hold the value as described below.

- `SE_STRING`

The value is a string and maps to the `secharptr` typedef described below.

- `SE_BUFFER`

The value is a buffer, a special ScriptEase array of bytes. It maps to `ubyte *`.

- `SE_OBJECT`

The value is an object. ScriptEase objects are identified by the `seobject` typedef handle.

---

## sebool

A boolean value, it can be either `TRUE` or `FALSE`.

---

## senumber

This typedef represents a number. The build mode based on the [JSE\\_FLOATING\\_POINT](#) macro definition, either floating-point on or off, determines if this typedef is an integer or a floating-point value. See the documentation on [FLOATING POINT CUSTOMIZATION](#) for more information on redefining `senumber`.

---

## seobject

A handle to a ScriptEase object.

Note that `seobject` handles cannot be directly compared using the C `==` operator. To determine if two `seobject` handles refer to the same object, use the `seCompare` API function. Pass the two handles each with `SE_VALUE` as the member and `SE_COMP_EQUAL` as the test condition.

---

## sestring

An internalized ScriptEase string. Member name strings are entered into the ScriptEase string table and the result is an `sestring`. `sestrings` can be directly compared for equality using the C `==` operator.

---

## secharptr

You should not use `char *` in your programs, use `secharptr` instead. This typedef gives you a pointer to a string of the correct type for the build mode. String constants should be encased in the `UNISTR()` macro. While `"foo"` is a literal of type `char *`, `UNISTR("foo")` is a literal of type `secharptr`. If you insist on writing your literals without the `UNISTR()` macro, your program will not build correctly on Unicode or MBCS systems.

All standard library functions that take a `char *` parameter have a version that takes an `secharptr`. Append to the name of the function `_sechar`. For instance, `sprintf` only works on ASCII ScriptEase builds while `sprintf_sechar` works on all builds.

---

## seconstcharptr

An `secharptr` in which the string contents are constant. Note that writing `const secharptr` instead generates an unchangeable pointer.

---

## sechar

## secharptrdatum

A single character. `sechar` is the maximum size of a character, such that an array of `sechars` of size `X` can always hold a string of size `X`.

`secharptrdatum` is what an `secharptr` points to. Such an array does not point to `sechar` necessarily. For instance, on MBCS, strings and thus `secharptr` point to an array of characters (bytes). However, each MBCS logical character may take up several of those bytes. Therefore, `sizeof(sechar) > sizeof(secharptrdatum)` for MBCS builds.

---

## sememcount

A count of things that is based on the address range on the system. This represents things like the number of bytes an `secharptr` takes up. This is an unsigned value.

---

## sesmemcount

The signed version of `sememcount`.

---

## SE\_CALLBACK()

Any function that you write which may be called by ScriptEase must use the `SE_CALLBACK()` macro. Put the entire return type of the function inside the macro, for instance:

```
SE_CALLBACK( const void * ) myfunc();
```

---

## THE CHARACTER ACCESS ROUTINES

In order to access individual characters in `secharptrs`, the following macros must be used. If you access the characters using the standard C notation, such as `+` for indexing and `[]` for accessing, your code will fail on MBCS builds. The following macros are provided instead:

### SECHARPTR\_INC(string)

Increment an `secharptr` string pointer.

### SECHARPTR\_GETC(string)

Get the character pointed to by the `secharptr` string pointer.

### SECHARPTR\_PUTC(string,char)

Put the character to the `secharptr` string pointer.

### SECHARPTR\_OFFSET(string,offset)

Get an offset into an existing string. The offset is in characters. The string must be initialized such that the offset is not past the end of the string.

### SECHARPTR\_NEXT(string)

A faster way to do an `SECHARPTR_OFFSET()` of 1 character.

### SECHARPTR\_DIFF(string1,string2)

Get the difference in characters between the two string pointers. They must point into the same initialized string, and the first string pointer must be later in that string than the second string pointer.

# Initialization and Contexts

Initialization is necessary before you can actually perform the tasks related to executing scripts. The first task is to initialize the engine itself. Your application only does this once when it starts and terminates the engine once when it exits. Even if you are running multiple threads in your application and running many different scripts, you only initialize the engine once. Here is a code snippet demonstrating initializing and terminating the engine:

```
void
main(int argc, char **argv)
{
    seInitialize();

    /* your application, including scripting. */

    seTerminate();
}
```

The other initialization task is to create an `seContext`. This is a handle that ties all of your scripting together. Each script you wish to run needs a context. It holds the variables, functions, preprocessor defines, and all the other information a script needs. You, as the API user, pass an `seContext` whenever you make a ScriptEase API call.

A single context may run more than one script one after the other but not simultaneously. If you want to run multiple scripts at once, such as in a multithreaded application, each thread will need its own context. You can create as many contexts as you like. Most applications will create a single context that is used for the life of the application then destroyed.

A newly created context will have all of the standard function libraries available for scripts in it to call. You determine which are available by your `jsseopt.h` file as is discussed in the "[Integration Into Your C/C++ Application](#)" chapter. When the context is created, these functions are added to the global object. In JavaScript, global variables are just the members of an object, the global object. Any scripts running can see the stock libraries as global variables. This is how a script access stock objects like `eval`, `Math`, `String` and so forth.

To create a context, you must use the `seCreateContext` ScriptEase API call. The only required information for all versions is an `seContextParams` structure. You must fill one out and pass it as a parameter to `seCreateContext`. This structure is copied into the context on creation. The second parameter is a string. If you are using a trial version of the ScriptEase ISDK, you must give your userkey provided to you by Nombas. If you do not, the trial version will fail in its construction of a new context and return `NULL`. If you have a purchased version of ScriptEase, this second parameter is ignored.

## The `seContextParams` Structure

The `seContextParams` structure contains a number of members which you must initialize. Most of them can be `NULL` to indicate no interest in that member. However, the `sePrintErrorFunc` member is a required member. Each member is listed in the order it appears in the structure along with a description of it. For

members that are callback functions, the function's prototype is given. The member of the `seContextParams` structure must be filled in with a pointer to a function that matches that prototype.

For many of these functions, you can find a sample implementation in the `src\app` directory of the ScriptEase distribution which you may use or modify.

```
SE_CALLBACK( void )
sePrintErrorFunc(secontext context, seconstcharptr text);
```

This function is called by the core to print an error to the user. This happens when a script generates an error that is not trapped by a `try/catch` handler. The error needs to be displayed to the user. This is the function that is called by ScriptEase to do so. This parameter is not optional, you must include an `sePrintErrorFunc` in your parameters.

```
SE_CALLBACK( void )
seAtErrorFunc(secontext context, struct seAtErrorInfo *info);
```

This optional callback is invoked whenever a script generates an error, at the point of error. This will occur for any error, even if the error is trapped via a `try/catch` handler. Note that some scripts will throw errors as a valid part of their program such as to indicate an error return from a function which will be trapped higher up in the script. This is why normally you do not care about an error until it comes back to you via the `sePrintErrorFunc`, indicating it never is trapped. Getting an immediate notification is primarily useful in implementing a debugger for which the user may want to stop anytime an error is generated even if it will be handled, in order to step through the handling code.

The `seAtErrorFunc` is passed an informational structure about the error. Here is the definition:

```
struct seAtErrorStruct
{
    sebool trapped;
};
```

Currently, the structure has only a single member. The boolean `trapped` is `TRUE` if the error will be trapped and `FALSE` if the `sePrintErrorFunc` will be called on it.

The actual value of the error is set up in the `SE_RETURN` object which is described fully in "[SE\\_RETURN EXPLAINED](#)". For an error, the value is an `Error` object as described by the ECMAScript specification. Since working with variables and return values is not described until later chapters, you should revisit this description once you have read those chapters.

```
SE_CALLBACK( void )
seContinueFunc(secontext se);
```

This optional function is called by the ScriptEase interpreter after every statement while evaluating scripts. It is useful to perform periodic work, such as checking Windows messages in a Windows ScriptEase application. It is also useful in implementing a debugger to regain control after each statement is executed.

When evaluating scripts using `seEval` (described in "Using `seEval`"), you can pass the `SE_INFREQUENT_CONT` flag to have the continue function called much less frequently than once per statement. If all you need to do is an occasional Windows Message processing, calling this function after every statement wastes a lot of processing which is when this flag is most useful.

You use the standard ScriptEase wrapper return rules to control execution using this function. You can return an error in the normal way which will abort script execution but can be trapped like any other error. Alternately, you can use set the object,member pair `SE_RETURN`, `SE_EXIT` to `TRUE` in order to force the program to abort completely. Returning a non error value does nothing, it is ignored. Either you generate an error in order to abort script execution, or you return nothing and the script continues as normal.

```
SE_CALLBACK( sebool )
seFindFileFunc(secontext se, seconstcharptr fileName,
               secharptr fileResults,
               sememcount fileResultSize,
               sebool lookForExtlib);
```

This optional function is used by ScriptEase when looking for source files. The filenames being looked for are the filenames passed to the `#include` and `#link` directives. The parameter `lookForExtlib` tells you which kind if being looked for: `TRUE` for a `#link` extlib, `FALSE` for a `#include` include file.

If you do not implement this function, then files are looked for directly, meaning that the filename given must appear exactly as specified in the current directory. By implementing this function, you can handle looking for these files with various extensions in various directories. You are passed `fileName`, the file to be looked for. This is the text that appears in the directive exactly as the user entered it. You fill in the `fileResults` buffer (the parameter `fileResultSize` tells you how big the buffer is) with the translated filename and return `TRUE` to indicate the file is found. If you return `FALSE`, you specify the file as not found. See the `seGetSourceFunc` below for more file-related behavior.

```
SE_CALLBACK( sebool )
seGetSourceFunc(secontext se, struct seSourceInfo *info,
                uint mode);
```

This optional callback is used to read script files. If you do not provide the callback, files are read using the normal C I/O functions; `fopen`, `fgets`, `fclose`. By defining this function and the `seFindFileFunc` above, you can completely virtualize your files. Although you can handle the virtualizing of files in this function alone, error reporting is based on the filename returned from `seFindFileFunc` so implementing it is recommended for the user's ease. In addition, you will need to implement `seFindFileFunc` to locate extlibs, which once located are loaded by a system call.

The `mode` parameter tells you what the call is intended to do. It can be one of these values:

<code>seSourceOpen</code>	open a new file
<code>seSourceGetLine</code>	get the next line from the file
<code>seSourceClose</code>	close the file

The `info` parameter points to a structure that you fill in accomplish these calls. Note that each file will be given its own `seSourceInfo` structure to work with. In each case, the `seSourceOpen` routine is called. Returning `FALSE` results in an 'unable to open file' error in the script. Next the `seSourceGetLine` is called repeatedly to get the individual lines of the source until you return `FALSE` to indicate no more lines. Finally, `seSourceClose` is called to close down the file.

The `seSourceInfo` structure is as follows:

```
struct seSourceInfo
{
    secharptr          lineText;
    const seconstcharptr filename;
    uint              lineNum;
    void *             userdata;
};
```

`filename` is preset by `ScriptEase` and should not be modified. It is the result of the `seFindFileFunc`. `lineText` is where the application should return the successive lines of the file including the newline character on each line. It is a pointer to a buffer that the application will allocate and presumably free in the `seSourceClose` processing. `lineNum` is the line number of the file which the application should update as it returns lines. Finally, the `userdata` is where the application keeps whatever information it needs to process the file. A simple implementation would use a `FILE *` for `userdata`, but a more complex one might need to point to a structure keeping necessary data.

```
SE_CALLBACK( sebool )
seGetResourceFunc(secontext se, sint id,
                  secharptr buf,
                  sememcount buflen);
```

`ScriptEase` uses a number of text string resources, which it has internal string values for. You can use this optional callback function to override those values. This is useful for internalization, to translate the text strings into whatever language is appropriate. The `id` parameter indicates which resource `ScriptEase` is trying to access. You fill in the `buf` with the text you'd like to give the resource. The `buflen` tells you how much space `buf` points to.

The list of identifier numbers and the English strings corresponding to them can be found in `src\core\rsrc\core.h` and `src\lib\common\rsrc\lib.h`.

```
SE_CALLBACK( void )
sePrepareContextFunc(secontext se);
```

After `seCreateContext` has finished preparing a new context, it invokes this function. You can do any final setup on your context here, such as adding your application specific wrapper tables (see "[Wrapper functions](#)"). If you do the final preparation here instead of in your code after calling `seCreateContext` then all calls to `seCreateContext` will do that same preparation. This is useful if you are using utility libraries that create new contexts with `seCreateContext`. It ensures those contexts are properly set up for your application. `Nombas` has no utility routines that use `seCreateContext`. However, some may be created in the future.

```
uword32 seOptions;
```

The options parameter is a flags parameter, you can use any combination of the following |'ed together:

#### SE\_DEFAULT

Default behavior

#### SE\_OPT\_REQUIREVAR

All variables must be declared using the `var` keyword. If this flag is not used, the normal JavaScript behavior is in effect. When you write to an undeclared variable, the variable is automatically created as a global variable. Reading from an undeclared variable always results in an error.

#### SE\_OPT\_DEFAULTLOCAL

Variables used without declaring them with the `var` keyword are declared automatically as global variables as described above under `SE_OPT_REQUIREVAR`. This flag makes them declared as local variables instead. JavaScript standard behavior is to create the variables as global variables.

#### SE\_OPT\_WARNBADMATH

If any math operation involves NaN, an error will be flagged. Normally, JavaScript allows NaN to be used in an operation and defines specific results.

#### SE\_OPT\_EXTRAPARAMS

Wrapper functions indicate the maximum number of parameters they can take, and extras will cause an error. This flag causes all library functions to take any number of parameters, ignoring excess parameters. It is normally useful to leave out this option, as extra parameters usually signal an incorrect usage of these functions.

#### SE\_OPT\_TOBOOLOBJECTS

JavaScript states that any object converted to a Boolean results in `TRUE`. If this flag is on, objects are first converted to a primitive then to a boolean. For instance, without this flag the object `new Boolean(False)` or `new Number(0)` will convert to `TRUE`, but with the flag they become `FALSE`.

#### SE\_OPT\_DEBUGGER

A debugger is in use, so ignore `SE_INFREQUENT_CONT` for all `seEval` calls.

#### SE\_OPT\_NO\_LIBRARIES

Creates the context but does not initialize the libraries into it. Useful when sharing libraries via the global `_prototype`.

#### SE\_OPT\_REQ\_SEMICOLON

Disables the EcmaScript rules of automatic semicolon insertion, as described in section 7.9 of the EcmaScript Language Specification. With this flag set errors will be generated on any statement that is not terminated with a semicolon.

Here is the example from above extended to create a single context:

```
SE_CALLBACK( void )
my_error_printer(secontext se,seconstcharptr text)
```

```

{
    printf_sechar(UNISTR("Error encountered: %s\n"),text);
}

void
main(int argc, char **argv)
{
    secontext se;
    struct seContextParams params;

    seInitialize();

    memset(params,0,sizeof(params));

    /* The print error function is the one required function.
    */
    params.sePrintErrorFunc = my_error_printer;

    se = seCreateContext(&params,MY_JSE_USER_KEY);

    /* your application, including scripting using 'se'
    * as the scripting context.
    */

    seDestroyContext(se);

    seTerminate();
}

```

# Working with Variables

The ScriptEase engine keeps track of all variables used by the scripts you execute. The ScriptEase API provides functions to examine and modify these variables. The most common place you will use these functions is in the body of wrapper functions which are described in the next chapter. However, that is not the only place you might want to examine variables. For instance, the ScriptEase debugger executes scripts one statement at a time and lets the user examine the variables as it is doing so. The debugger uses the ScriptEase API to do this.

The most important concept to remember is that every variable is a member of some object. There are only a few top-level objects that store all variables and values used by ScriptEase. For instance, if a script says:

```
var a = 4;
```

That global variable `a` is a member of an object, the global object, which is one of these top-level objects. All global variables are members of this same object. Similarly, functions can have local variables and parameters, such as in this function, which are also part of an object:

```
function foo(b)
{
    var c = 10;
}
```

This function has two variables, the parameter `b` and the local variable `c`. Both are part of an object called the activation object. Each time a function is called, a new activation object is created for it. There is one global object but there can be many activation objects. Activation objects are created for a function when it starts executing and destroyed when the function finishes. The ScriptEase API lets you access all activation objects, so you can examine or modify all local variables for functions currently being run.

---

## IDENTIFYING A VARIABLE

The majority of ScriptEase API functions work with variables, retrieving or modifying their values. All the functions share a common way to identify which variable you want to work with. You specify the object and member that the variable resides at as parameters to each function. ScriptEase provides a number of predefined objects that you can use which cover all of the places variables are stored internally. The most common is `SE_GLOBAL`, the global object. Each such object is fully explained below. Note that `SE_GLOBAL`, `SE_THIS`, and so forth are the names of the object. You pass that exact text to the function to identify that as the object you want to work with.

Later, when we discuss the API functions for examining variables, we will see it is possible for a variable itself to be an object. In that case, `seGetObject` will return an object handle for the object the variable contains. This handle, since it is an object, can be used instead of `SE_GLOBAL` or the other stock objects in further variable identifications. In this way, starting from the top-level objects you can access any variable on the system.

While it is possible to access any variable in this way, it is not always convenient. For instance, let's say you want to get at the variable `foo[5].goo`. You could do this in steps. You would get `foo` as a member of the global object. After seeing that it is itself an object, you could get the numeric member `5` from it. That gives yet another object from which you could extract the final member `goo`. Not only is that ugly and difficult to understand, but there could be other caveats. A script, when it refers to `foo`, might not be getting a global variable. `foo` could be a local variable, or it could be found because the code is inside a `with` statement. Trying to program all the possibilities would be tedious, lengthy, and error prone.

Fortunately, ScriptEase provides an API call to do this for you. `seVarParse` will take an arbitrary variable name, such as `a` or `foo[5].goo` and tell you what object and member name it is referring to. Once you have the object and member name, you are ready to call any of the variable access functions we will describe below to examine or modify that variable. Most of the API function that take an object/member pair can also use the `SE_COMPOUND` types to parse arbitrary variable names.

## LIST OF MEMBER SPECIFIERS

The second half of the variable locator is the object member to access. We will discuss specifying that first as doing so reduces the number of forward references.

When you want to access a member of some object, you use one of the following macros to indicate which member you'd like to access.

### **SE\_MEM("member name")**

The simplest form, this accesses the named member of the object.

### **SE\_UNIMEM(seconstcharptr)**

This member access specifier takes an `sechar` string such as an `sechar []` or an `secharptr`.

### **SE\_HIDDEN\_MEM("member name")**

This is identical to `SE_MEM` except that the member accessed is visible only to the ScriptEase API, and not to the scripts themselves. These hidden members are an excellent way to associate data with an object (such as a C pointer) that you don't want to be seen by the script.

### **SE\_HIDDEN\_UNIMEM(seconstcharptr)**

Like `SE_UNIMEM` but the member is hidden from the scripts. See `SE_HIDDEN_MEM`.

### **SE\_COMPOUND\_MEM("compound.member.name")**

Similar to `SE_MEM` but the member name can represent complex expressions. See `seVarParse` for limits on these expressions.

### **SE\_COMPOUND\_UNIMEM(seconstcharptr)**

Like `SE_UNIMEM` but member expression can be compounded. See `seVarParse` for limits on these expressions.

### **SE\_NUM(sememcount)**

Allows you to access numerically-named members. This is most useful with arrays. Because of the way JavaScript works, member names that are number use the text representation of that number as their name. Thus, `SE_MEM("10")` and `SE_NUM(10)` refer to the same member. Because of internal optimizations, not only is this naming method more convenient for numeric members, it is faster. Note that this method may only be used for non-negative numbers. For negative numbers use a string method (e.g. `SE_MEM("-1")`).

### **SE\_STR(sestring)**

Accesses a member using an `sestring` internalized string that was received from the ScriptEase API. You can generate such strings using the `seInternalizeString` or `seInternalizeStringHidden` API call. Member names passed to callback functions are in this format.

An `sestring` is faster to use than a string literal member name. When you pass a member name using `SE_MEM`, it has to be converted into an `sestring` internally before continuing. Doing it once and referring to members using the resulting `sestring` is faster. In addition, you can compare `sestrings` for equality using the `==` operator which is much faster than the `strcmp_sechar` needed to compare text strings.

### **SE\_INDEX(num)**

Internally, all objects members are stored in slots. They are contiguous starting from 0. `SE_INDEX` lets you access a member by its slot.

The usual use for this method of accessing members is to iterate over all members of an object. The ScriptEase API call `seObjectMemberCount` will tell you how many members an object has and thus how many slots it is using. Those slots are numbered from 0 to one less than the number of slots.

Note that the slot a particular member uses will change as members are added to or removed from an object. Do not try to use `SE_INDEX` to access regular members or assume they occupy any particular slot.

### **SE\_STRUCT(memdesc)**

You can use this macro to retrieve the member from an `seMemberDesc` structure and pass it to any of the functions. You store a member in the structure using the `seStoreMember` function. Here is a short code example:

```
struct seMemberDesc mem;
seStoreMember (& (mem), SE_NUM(0));
sePutNumber (se, myObj, SE_STRUCT (&mem), 10);
```

Member description structures are useful to pass a member identifier as a parameter to a function.

### **SE\_VALUE**

`SE_VALUE` means not to work with any member but rather to work with the object itself. For instance, you can use the object,member pair `SE_GLOBAL, SE_VALUE` to examine or change the global object. For most objects, putting a value to the object itself using `SE_VALUE` will call the operator overload function on that object with the operator `SE_OP_ASSIGN` being overloaded. If the object has no operator overloading, then the operation does nothing and is ignored. Several of the special ScriptEase objects have their own

behavior when assigned to the `SE_VALUE` member. For instance, with `SE_GLOBAL` doing so changes the global object. Read the individual descriptions below of the ScriptEase objects to determine if that object allows a put to itself via `SE_VALUE` and what that put does.

### **SE\_STOCK(string)**

There are a number of stock member names which are accessed via this macro. The text of such a stock string is put as the argument to the macro such as `SE_STOCK(length)` or `SE_STOCK(this)`. For a particular string, such as `length`, `SE_STOCK(length)` is equivalent to `SE_MEM("length")`. The advantage to using the `SE_STOCK` macro is that the macro is faster. However, only some of the more commonly used member names are available with `SE_STOCK`.

All of the stock strings may be found in the file `src/misc/stockstr.h`

### **SE\_FUNCTION\_TEXT**

This is a special member that cannot be created, written to, or deleted. Only script functions have this member, for all other objects `SE_FUNCTION_TEXT` is undefined. The value associated with the member is a text version of the script function's body.

Some builds, such as when `JSE_SAVE_FUNCTION_TEXT` is not defined (the default if `JSE_MIN_MEMORY` is defined), do not save the information necessary to rebuild the function's text representation and therefore will always return an undefined value.

### **SE\_FUNCTION\_GLOBAL**

If `JSE_MULTIPLE_GLOBAL` is defined, then this flag can be used with functions to retrieve or assign the global object that will be associated with that function. `SE_NOWHERE` will be used if the function object should not set the global on entry/exit.

For example, to disable global variable switching on a function named "anonymous":

```
seobject anon;  
anon = seGetObject(se, SE_GLOBAL, SE_MEM("anonymous"));  
sePutObject(se, anon, SE_FUNCTION_GLOBAL, SE_NOWHERE);
```

### **SE\_LIBRARY\_DATA**

All wrapper functions have a piece of user data associated with them determined by the [seAddLibTable](#) call that initialized that function. Use `seGetPointer` to retrieve that data from a wrapper function. Only wrapper functions have library data associated with them.

## **LIST OF STOCK OBJECTS**

ScriptEase scripts contain a large amount of data you might want to access. You access a particular piece of data using one of the following stock object. The name given is the value you pass as the `object` parameter to any of the variable accessing functions described below. After each object name listed below is a description of that object and what data you will actually be getting or changing when you access and modify its members.

## SE\_GLOBAL

The members of this object are the global variables of the script. For instance, the global variable `zed` is the member `zed` of this object. You can examine and change global variables by using this stock object. You can also change the global object itself by using `sePutObject` on `SE_GLOBAL`, `SE_VALUE`.

Note that all functions remember the global object in effect when they were first created and swap that in when they are executing. This facilitates scoping where multiple scripts are executed using `seEval` each with a new global object. The various functions remember their global object so that variables created with the `var` keyword in the script the function was evaluated in are accessible whenever the function is executing. For some programs, this behavior is undesirable. For instance, a person might want to create utility functions that always act on the variables currently in effect and thus run them with the current global objects. There are two ways to change the behavior.

First, by turning off `JSE_MULTIPLE_GLOBAL` in your `jseopt.h` file, this behavior is turned off completely. Alternately, you can turn the behavior off for any wrapper function by including the `SE_KEEP_GLOBAL` flag in the function flags used to define that wrapper function (see chapter on "[Wrapper functions](#)" for more details.)

## SE\_ARGS

The members of this object are the arguments passed to your wrapper function. If you are outside a wrapper function, this object has no members. You cannot add or delete members from this object, you can only access and update the actual parameters passed to your function.

Since ScriptEase supports named arguments, you can specify a normal member name. However, most wrapper functions have no names for the arguments, and names are only present if the caller provided names for the arguments. Normally, you just use `SE_NUM(x)` to access argument number `x`. For instance, `SE_NUM(0)` is the 0th argument (i.e. the first argument passed to your function) and so forth. For the arguments object, `SE_INDEX` accesses the members just like `SE_NUM` does, they are synonymous.

You cannot use `SE_VALUE` with `SE_ARGS`.

## SE\_ACTIVATION

An activation object is the object used to store local variables and parameters to a function. Since a wrapper function is written in C, it has no such variables. However, the calling script function does, and it is often convenient to be able to access them. `SE_ACTIVATION` accesses the calling script function's activation object. If there is no calling script function, `SE_ACTIVATION` accesses the global object, just as `SE_GLOBAL` does. You can get the activation object by using `SE_ACTIVATION`, `SE_VALUE` but you cannot write to it.

## SE\_THIS

Whenever a function is called, it has a `this` variable associated with it. For instance, when you call a function such as:

```
foo.func();
```

`foo` is the `this` variable for the function call to `func()`. When you don't specify an explicit `this` variable, such as:

```
func();
```

The `this` variable is implicitly the global object. You can access the `this` variable for your wrapper function, which is always an object, and its members by using the `SE_THIS` stock object. If you use `SE_THIS` outside of a wrapper function, it is always the global object.

You cannot write to `SE_THIS`, `SE_VALUE`, it is read-only.

## **SE\_SCOPE**

Using `SE_SCOPE` is a way to locate a variable in the same way that the script interpreter would, following the `__prototype` and `__parent` chain of the active functions. If you know for certain what object a member belongs to (some object or `SE_GLOBAL` or `SE_THIS` for example), then using that object directly is more efficient, but `SE_SCOPE` mimics the flexible scoping rules of the ECMAScript language.

## **SE\_TEMP**

Often a ScriptEase API program needs to create variables of its own to store temporary data. `SE_TEMP` refers to an object where such data can be stored. This object lasts for the life of the context, so your data can be long lasting if you desire. You are free to add and remove members from this object as you need. Please see the in depth explanation of this object later in this chapter.

You cannot write to `SE_TEMP`, `SE_VALUE`.

## **SE\_WRAPPER\_TEMP**

Like `SE_TEMP`, but the object and all of its members goes away when the current wrapper function finishes. If used outside of a wrapper function, it is identical to `SE_TEMP`. Like `SE_TEMP`, you cannot write to the object itself.

## **SE\_NOWHERE**

This is a garbage sink object. Any write to any member of this object is ignored, as are attempts to create new members. Any read of a member returns the undefined value. It is intended for one particular use, namely as a return from functions that return an object,member pair when there is an error. If the programmer doesn't check the error return and just tries to use the returned object,member, a `SE_NOWHERE` member is returned so the access does nothing and doesn't crash.

If you compile the core with the `SE_TRAP_NOWHERE` option on, accesses to this object will trigger assert failures. This is intended to facilitate debugging, to find where you have not properly checked your returns from ScriptEase API calls.

## **SE\_DEFINES**

The `#define` statement defines a macro, an identifier mapped to be a different value. Note that ScriptEase does not support parameterized macros. This object's members are the defined macros, the value of the members are strings that are what the macro is defined to be. In other words, if you have this statement:

```
#define FOO goo
```

Then one of the members of the `SE_DEFINES` object will be `FOO` and its value will be the string `"foo"`. You can examine and modify the defines as well as add new ones by creating new members. Note that these defines will only affect scripts that are executed after you make the change.

You may not write to the `SE_DEFINES` object itself.

## **SE\_RETURN**

This is the place in which the return value from your wrapper function is to be stored. This discussion will only be minimal for now, a more complete discussion of this object can be found later in the chapter. `SE_RETURN` mainly works with the `SE_VALUE` member. For the return, the `SE_VALUE` is the value to be returned. That is to say, if you want to return the value `10`, you would write:

```
sePutNumber(se, SE_RETURN, SE_VALUE, 10);
```

The object has four secondary members, all of which are booleans. You set one (and only one) of them to `TRUE` to indicate a special return condition. They are:

## **SE\_ERROR**

The returned value indicates an error. If this flag is `FALSE`, the value returned in `SE_VALUE` is a normal return like the JavaScript statement `return 10;`. If this flag is `TRUE`, it is the equivalent of `throw 10;`.

## **SE\_EXIT**

Exits out of the script with the returned value being the return of the script. This is exactly analogous to a C program calling `exit()`, for instance `exit(10);`.

## **SE\_YIELD**

Causes the script to drop back to the calling `seExec` API call. This is useful for fibers, described in "[Fibers and Threads](#)". It will allow the next fiber to take its turn. The return value is still returned as normal once the fiber gets its next turn to run.

## **SE\_SUSPEND**

Similar to `SE_YIELD`, in that the fiber drops back to the calling ScriptEase ISDK application. However, the fiber cannot be run until resumed by the application. Any calls to `seExec` will return immediately. The application restores the fiber by putting `FALSE` to that fiber's `SE_RETURN`, `SE_SUSPEND` member. In addition, the application may also modify the return value after it does so, but before it `seExecs` the fiber. This is useful for implementing wrapper functions that delay the fiber until some needed value is available, then return that value. The application manager can examine the wrapper function's return value to allow the wrapper function to communicate with the manager. The chapter on "[Fibers and Threads](#)" has more details.

In addition to a place to put your return, the `SE_RETURN` object is also where you receive the result from `seEval` API invocations. The reason for the dual use is simple; in many cases, you want to execute some code using `seEval` then pass along the result. By putting it in this place, you can immediately return from your wrapper function, returning that value.

Note that once `SE_ERROR` is set to true, the return value is locked into place and cannot be changed. The reason is again for convenience. Many times you want to just run your snippet of code and not check for errors. In this way, if an error

occurs, it takes precedence. You don't have to check for the error to avoid overwriting it. However, you can reset the `SE_ERROR` boolean back to `FALSE` if you want to erase the error and overwrite it.

## **SE\_AT\_EXIT**

The `SE_AT_EXIT` object contains a number of members who are functions, wrapper or script. These functions should take no parameters. All of the function members are invoked when the current `seEval` with the flag `SE_EXIT_LEVEL` completes. The `this` object for these functions will be the `SE_AT_EXIT` object they are a part of.

Members of the `SE_AT_EXIT` object that are not functions are ignored. However, they can be used to store information to be retrieved by an at-exit function through its `SE_THIS` object.

The `sePutWrapper` API function is useful for creating functions as members of the `SE_AT_EXIT` object to then be called.

You should choose member names for your at-exit functions that are unique and unlikely to be duplicated. Using short, common member names runs the risk of overwriting another at-exit function or its associated data members.

## **SE\_FILENAMES**

This object is an array, so it has members 0, 1, and so forth. Each member's value is a string, one of the filenames the script is using. These filenames are the source files of the script. Because a script can use the `#include` directive, a script can be made up of several source files.

## **SE\_STACK\_INFO(depth)**

These objects contain information about all function calls currently being executed. `SE_STACK_INFO(0)` represents info on the wrapper function you are in, `SE_STACK_INFO(1)` is the function that called you, and so forth. The maximum depth you can look back is determined by the compile-time constant `SE_MAX_STACK_INFO_DEPTH` which defaults to 64. Thus, by default, you may use `SE_STACK_INFO(0)` to `SE_STACK_INFO(63)`.

Here are the members of each stack info object and what that information is. These members are all read-only:

## **SE\_SI\_WRAPPER**

A boolean, `TRUE` if the function is a wrapper function, `FALSE` if it is a script function.

## **SE\_SI\_FUNCTION**

The object for the function.

## **SE\_SI\_FUNCNAME**

The string name of the function.

## **SE\_SI\_TRAPPED**

`TRUE` if an error occurring would be trapped if it occurred in this function.

## **SE\_SI\_GLOBAL**

The global object for this function.

## **SE\_SI\_THIS**

The `this` object for this function.

### **SE\_SI\_DATA**

The user data associated with this function if it is a wrapper function. This is `NULL` for script functions. You retrieve this value using `seGetPointer`.

### **SE\_SI\_FILENAME**

The filename the current line of the script function is in. For wrapper functions, this will be undefined.

### **SE\_SI\_LINENUM**

The line number of the current line of the script function, or 0 for wrapper functions.

### **SE\_SI\_ACTIVATION**

The activation object for the script function. For wrapper functions, it will be the same as the global object.

### **SE\_SI\_SCOPECHAIN**

The current scope chain for the script function. See "[Script Execution Topics](#)" for more information on scope chains.

### **SE\_SI\_DEPTH**

The depth of the function. As you go deeper into the stack, the depth gets smaller. For instance, if a script is in a wrapper function called from the main body of the stack, then the call stack comprises two levels, `SE_STACK_INFO(0)` and `SE_STACK_INFO(1)`. The `SE_SI_DEPTH` is indication of how many function calls are nested beneath this level, including the level itself. In this case, the `SE_SI_DEPTH` of `SE_STACK_INFO(0)` will be 2, indicating 2 items nested. The `SE_SI_DEPTH` of `SE_STACK_INFO(1)` will be 1, as this function has only itself and nothing nested beneath it. The depth can be 0 if `SE_STACK_INFO(0)` is used while no code is executing and thus no function calls are nested at all.

### **SE\_SERVICES**

This is a storage space to associate names with arbitrary data. What data you associate is reserved for your application. ScriptEase: Desktop, for instance, stores a number of pointers with names.

You are allowed to retrieve and store values to `SE_SERVICES`, `SE_VALUE`. This is a single slot that is accessed more quickly than the others. However, there is only one such slot. Therefore, an application writer is given that slot for his application. Any utility function library that need to associate data with a context must use a named member of the `SE_SERVICES` object to store its data.

### **SE\_SHARED\_SERVICES**

This object is used in the ScriptEase builds that allow objects to be shared among contexts. In builds in which this is not turned on, it is a synonym for `SE_SERVICES`. This means you can use this object to make your code work correctly when shared and still compile and function in a non-shared build.

See the **SHARED SERVICES** section in the [Fibers and Threads](#) chapter for a complete discussion of sharing objects and using this stock object.

### **SE\_SELF**

A wrapper function can use this object to refer to itself, the wrapper function that is currently executing. It is used most often to retrieve the library data for the executing wrapper function using the `SE_SELF`, `SE_LIBRARY_DATA` pair.

---

## EXAMINING VARIABLES

Now that you know how to select the variable you are interested in, let's look at examining its value. JavaScript does not have variables of fixed type. When a script is run, any variable can be assigned a value of any type. Each can be assigned values of differing types as the script continues. For this reason, you have to look to see what type a variable currently is. You do this using the [seGetType](#) API call. This tells you what type an object member is. You can use this information to execute different code based on the type of a variable.

Fortunately, you can let ScriptEase worry about converting types and just ask to get a variable's value as a certain type. If the variable is not of the correct type, it is converted. This is useful because many JavaScript functions are designed to work this way; when passing parameters to the standard JavaScript functions, they are converted to the type the function expects automatically. If you allow ScriptEase to do the same when you are accessing variables, you will automatically follow the JavaScript standard that variables are converted to the correct type whenever necessary. The `seGetXXX` functions, where `XXX` is based on the type you'd like to get, convert the ScriptEase variable value to the given type and return it to you, in C format. Note that the variable is not permanently changed. You can use the `seConvertXXX` API call to do that.

All of the API calls that read a variable's value, either to get its type or get its value, read the value exactly once per API call. This is important to understand the behavior of dynamic objects. If you just use `seGetXXX`, the value is read, converted to the required type, and returned to you. This is the preferred method. However, you may want to read the type then get the value of that particular type, presumably to do different things based on the variable's type. Understand that this involves two calls to API functions that read the value, one to [seGetType](#) and one to a `seGetXXX`. This means the value will be read twice. If the object the member is being retrieved from is dynamic, that dynamic `get` will be called twice. It is possible for it to return two different values, defeating the purpose of your code.

In this situation, because `seGetXXX` is safe, your code will not crash just operate unexpectedly. You can ignore such objects and let the object's designer worry about it. Alternately, you can use `seAssign` to grab the value and store it in a temporary location. This will read the value once. Now you can use [seGetType](#) and `seGetXXX` on that stored value, knowing it will not change.

---

## MODIFYING VARIABLES

The other thing you do with variables is to change their value. You use `sePutXXX` to put a particular value into variable. Again, `XXX` has various options for the various types of data you can store in a variable. Like a JavaScript assignment, whatever value the variable held before the call is discarded in favor

of the new value. If the variable is a member of a dynamic object, a dynamic `put` will be called to store the value.

In the same way as for reading a variable's value, each API call that modifies a variable's value does so once, meaning one dynamic `put` call will be made per API function call. You can use a similar technique to reading, build up the value in a temporary location then put the value once to the real location, so any dynamic `put` is called only once.

---

## USING SE\_TEMP AND SE\_WRAPPER\_TEMP

Using these objects is pretty simple. You create a member, store some value in it, then delete it when you are done. For `SE_WRAPPER_TEMP`, you often do not delete the members explicitly and instead let them go away automatically when your wrapper function exits. The only problem arises in selecting which member to use. You need to ensure that you do not conflict with some other part of your program that may also be using a temporary member of these objects or with utility functions potentially written by someone else.

The way to do this is to choose a member name for your temporary variable that is not a simple name like `foo` or `i`. It is suggested that you use a name that incorporates the filename and wrapper function name, since that should be unique for your application. For instance, your member name might be `foo.c:my_wrapper.temp1`. In this way, you can ensure that your program does not mysteriously fail due to conflicting `SE_TEMP` member names.

---

## SE\_RETURN EXPLAINED

The `SE_RETURN` object is potentially the most confusing of the objects. However, it does not have to be. The main object,member pair associated with this object is `SE_RETURN, SE_VALUE`. This member is where you put the return value for your wrapper function. For instance, if you want to return the number 10, you would write:

```
sePutNumber(se, SE_RETURN, SE_VALUE, 10);
```

That part is easy. However, the `SE_RETURN` object has four other boolean members: `SE_ERROR`, `SE_EXIT`, `SE_YIELD`, and `SE_SUSPEND`. The last two are used for fibers and are covered in "[Fibers and Threads](#)". The first two are discussed next.

After you return a value (not before), you can mark that as an error result by setting the `SE_RETURN, SE_ERROR` member to be `TRUE`. Consider the JavaScript statement:

```
return 10;
```

versus

```
throw 10;
```

In the first case, the result is 10. In the second case it is also 10, but it is an error result of 10. If you don't understand the `throw` statement, you should consult a

JavaScript reference. The `return` statement is identical to the example we gave above. The `throw` statement is done from the ScriptEase API as follows:

```
sePutNumber(se, SE_RETURN, SE_VALUE, 10);
sePutBoolean(se, SE_RETURN, SE_ERROR, TRUE);
```

Throwing arbitrary values in this way is not common and is usually reserved for complex scripts. Most often, you want to throw an exception. Some error happens, such as illegal parameters to your wrapper function, and you want to generate an error return. That is a common occurrence, and ScriptEase provides the `seThrow` API call to do so. Explicitly setting `SE_RETURN`, `SE_ERROR` to `TRUE` is very uncommon, and you probably won't ever need to do it.

Similarly, the `SE_EXIT` flag indicates that the script should exit with the given value. Consider the C statement:

```
exit(10);
```

`SE_EXIT` is usually used to abort a script when an error occurs. Most of the time, you will use `seThrow` to generate an error. `seThrow` errors can be trapped using the `try/catch` statement allowing the script to recover from errors. However, if something so drastic has happened that the wrapper function decides the script must abort immediately and should not be trapped, you can duplicate the C `exit()` call using the `SE_EXIT` flag. This code does exactly that:

```
sePutNumber(se, SE_RETURN, SE_VALUE, 10);
sePutBoolean(se, SE_RETURN, SE_EXIT, TRUE);
```

There is one final thing you should know. Normally, you can keep overwriting `SE_RETURN`, `SE_VALUE`, and the last value returned is the result of the function. However, once any of the four boolean members is turned to `TRUE`, `SE_RETURN`, `SE_VALUE` becomes read-only. Any error is locked in this way. This means that if you call functions inside your wrapper function that generate an error, that error will also be the result of your own function, and propagated back to the user. This is usual desired behavior. In this way, you often do not need to check the error results of the ScriptEase functions you call, as those errors take precedence over whatever you try to return. This leads to small, easy-to-understand wrapper functions in most cases. If you have a more complex wrapper function that can recover from errors, you can unlock the error result by setting whichever of the four members that is `TRUE` back to `FALSE`.

# Script Execution Topics

Before we delve into customizing your scripting environment for your application, it's time to talk about the most common scripting operation: executing a script.

---

## Using seEval

Having created an `secontext`, you use this context to execute scripts via the ScriptEase API. The ScriptEase ISDK function to execute script code is `seEval`. This function has a large number of parameters to control its behavior and the behavior of executed code. This chapter is devoted to explaining `seEval`. Let's start with a simple example that uses default values for most of the parameters:

```
seEval(se,UNISTR("var a = 10;"),SE_TEXT,
      NULL,NULL,SE_DEFAULT,NULL);
```

All of the `NULL` values indicate a parameter that we are not interested in providing, using the default value instead. This call as it is written will evaluate the simple script `var a = 10;`. The full prototype of `seEval` is as follows:

```
sebool
seEval(secontext se,void *to_interpret,int interp_type,
      seconstcharptr text_args,
      seobject stack_args,
      uword32 flags,
      struct seEvalParams *params);
```

The function returns a boolean indicating whether or not the evaluation succeeded. It would not if the script to evaluate contains an error. In addition to indicating success or failure, the script returns a value using the `return` statement. This value returned from the script being called is stored in the `SE_RETURN` object. This means that if you invoke `seEval` in a wrapper function then immediately return from the wrapper function, the result of the evaluation is passed along as the result of your wrapper function. This is a useful technique which is used, for instance, to implement the ECMAScript `eval` function.

An important concept of an evaluation is that of the global object. All global variables in the script, as well as functions, are put into the global object. When the script completes, all variables and functions are still part of the global object. This means that additional calls to `seEval` will find the variables and functions from past calls. You can specify a particular global object in the `params` parameter to put these variables and functions in that object as is described below.

As was mentioned when describing error returns, once a context has an error as its return, any attempts to change the return value are ignored. Likewise, any calls to `seEval` are ignored for the same reason. It is the most reasonable course of action when some previous API call generated an error. You must first erase the error as was described if you want to use `seEval`.

Let's look at the parameters and explain their use.

## se

The first parameter, the context, is passed to every ScriptEase API function including this one.

## TO\_INTERPRET, INTERP\_TYPE

The second and third parameters are linked together. The third parameter, `interp_type`, indicates what the second parameter, `to_interpret`, is. Here are the possibilities:

```
INTERP_TYPE  TO_INTERPRET
-----
SE_FILE      seconstcharptr
SE_TEXT      seconstcharptr
SE_PRECOMP   ubyte *
SE_FUNC      seobject
```

`SE_FILE` indicates a filename, which is read, parsed, and interpreted.

`SE_TEXT`, which we've already seen above, indicates the source code is a text string.

`SE_PRECOMP` allows you to execute a precompiled script. You pass as the parameter the script buffer that was given to you by the `sePrecompile` ScriptEase API call.

`SE_FUNC` allows you to execute a function. You pass the function you wish to execute. Remember, in JavaScript, a function is just an object. You can retrieve the function you wish to call via the `seGetObjectEx` API call.

## TEXT\_ARGS, STACK\_ARGS

The next two parameters are likewise related. You can pass arguments to your script or function via one of them. `stack_args` takes precedence so if you use them both the `text_args` are ignored. In either case, the arguments are extracted and passed to the called script or function. For a function, these are just standard arguments. Script arguments are treated like `argc` and `argv` for the main function in a C program. They are stored for the script in the global variables `_argc` and `_argv`.

For text arguments, specify the arguments in a text string, i.e. `UNISTR("-v foo")`. This is parsed in exactly the same way as a command line; white space is used to separate the arguments, and each is turned into a string in the `_argv` array. For `stack_args`, you pass in a ScriptEase stack object created via the `seMakeStack` ScriptEase API call. The arguments are defined by setting members of this object numerically using the `SE_INDEX()` member format. In other words `SE_INDEX(0)` is the first argument, `SE_INDEX(1)` is the second, and so forth. This form of parameter passing is more commonly used for functions. Most scripts that handle arguments expect all of their arguments to be text strings. If you pass a script arguments that are not text strings, such as numbers or objects, you will probably confuse it.

When you call a function that passes any parameters by reference, the arguments in the stack object will be updated appropriately so you can check their final value before destroying the stack object after the function returns.

## FLAGS

The `flags` parameter is some or all of the following values, |'ed together:

### SE\_NO\_INHERIT

An eval is normally treated like the script text appeared in the containing script at the point it is executed. The script can see the same variables of its parent, change them, and so forth. If you use this flag, the eval is completely separate. It has no effect on its parent except to return a value.

If you use this flag, the stock libraries previously added to the parent will have new copies initialized for the child. See `SE_NO_LIBRARIES` below.

### SE\_NO\_LIBRARIES

Only used with `SE_NO_INHERIT`, the stock libraries are not made available. This flag is usually not useful as the script will not be able to call any of your wrapper functions. Still, you may want to just perform a computation that doesn't need to spend the time to reinitialize standard libraries that won't ever be called.

### SE\_NEW\_GLOBALS

If `SE_NO_INHERIT` flag is used, this flag is also automatically used. When the flag is not used, any new variable created is stored in the global object of the parent and is still around after this script finishes executing. If this flag is included, a new global object is created for variables the script uses, and those variables go away when the script completes. Specifying your own global variable in the `params` parameter overrides this flag.

### SE\_CALL\_MAIN

The ScriptEase extension of calling a function `main` after the evaluating the code outside any function will be used. If the flag is not included, a function `main` is not treated as special. This does not apply to calling a function.

### SE\_FUNCS\_ONLY

A script is executed in two parts. First, any functions defined in it are extracted and created. Likewise, any variables defined using the `var` keyword are initialized as undefined. This happens at the very start of the script. The second part executes any code in the script. For instance, consider this script:

```
function foo()
{
    return 10;
}

var a = 10;
```

A normal evaluation creates a function `foo` in the global object as well as a variable `a` as the undefined value. Then the code in the script is run, assigning `a` to be 10. If you specify the `SE_FUNCS_ONLY` flag, only the first part is executed. In this case, the function `foo` and the variable `a` are created, but the the script body is not run, so the assignment to `a` is not executed.

Understanding this behavior also is helpful in understanding a subtle ECMAScript rule, that all variables defined with the `var` keyword are extracted and initialized before any code is run to be the undefined value. In this script example, ECMAScript treats the script as if you wrote instead:

```

var a;

function foo()
{
    return 10;
}

a = 10;

```

### **SE\_EXIT\_LEVEL**

Normally, any new at-exit functions are added to the parent. This means they are not called when the `seEval` is done but rather when the whole context is cleaned up. If you turn on this flag, at-exit functions created inside the eval are called when the eval is finished.

This may seem like a good idea, but there is an important caveat. At-exit functions normally clean up resources. A call to `seEval` will return a value to you, and that value may be dependent on those resources. If the at-exit functions have been called, the value is using resources that have been cleaned up. This is why you usually want all at-exit functions held until the context is being destroyed, so you know all such values are no longer used.

### **SE\_NEW\_DEFINES**

Normally any new defines (i.e. MACROS) are added to a global list and will remain for any new `seEval` calls. This flag makes a new list only accessible to this evaluation for any new `#defines` defined in the script.

### **SE\_NO\_OLD\_DEFINES**

This flag will automatically turn on `SE_NEW_DEFINES` as well. Defines already created, such as by previous `seEval` calls, will not be applied to this evaluation.

### **SE\_REPORT\_ERRORS**

In many cases, you just want to interpret a script and continue. The script should print any errors and then you are ready to do something else. That's what this flag means. In other cases, you want whatever the call returns returned to you, even if it was an error. For instance, you may want to pass the result along, error or otherwise. In this case, don't include this flag and the return value of the called function will also be copied to your own return value.

### **SE\_INFREQUENT\_CONT**

Normally, the `seContinueFunc` function is called after each statement so debuggers can function properly. With this flag, it is called much less frequently. This is useful in Windows in which the continue function must check Window messages so the task doesn't get the 'not responding' problem. However, calling it after each statement wastes a lot of time. This flag causes the continue function to be called far less frequently.

### **SE\_START**

The script is initialized but not actually run. You use the `seExec` API call to execute one block of the script. `seExec` executes the script until the next time a `seContinueFunc` would be needed, so refer to `SE_INFREQUENT_CONT` above. The use of this flag is intended to allow easy cooperative multitasking within your application. You can call `seExec` to execute one small script piece at a time with whatever other code you desire between calls. You can run several scripts

simultaneously, each in their own `secontext`, by calling `seEval` on each with this flag set then calling `seExec` on each in turn.

## **SE\_CONSTRUCTOR**

This flag is only applicable if calling a function. `seEval` will then call the function as a constructor, i.e. as `new Func()` rather than `Func()`. The `this` you pass is usually `NULL`, in which case a blank version of the object type is created for the constructor, the default behavior when you do a `new Func()`. You can make the `this` something else in which case the constructor will get it. Watch out, this may confuse constructors. Also, some constructors ignore the provided object and create their own.

## **SE\_NAMED\_PARAMS**

Passes parameters by name. This can only be used if passing parameters in `stack_args`, and all the object members must have a name. You may use this flag only when calling a function.

## **SE\_INIT\_IMPLICIT\_THIS**

When this flag is specified, initialization code (i.e., global code that is outside of any function) will execute as if it is in a function with the `SE_IMPLICIT_THIS` flag set. This is useful when executing small pieces of code that need function-like scoping behavior such as browser event handlers.

## **SE\_INIT\_IMPLICIT\_PARENTS**

When this flag is specified, initialization code (i.e., global code that is outside of any function) will execute as if it is in a function with the `SE_IMPLICIT_PARENTS` flag set. Usually you will use this flag in combination with `SE_INIT_IMPLICIT_THIS`.

## **SE\_DEFAULT**

No special options.

## **PARAMS**

This parameter is a pointer to a structure that contains several optional variables. You can pass `NULL` to not specify any of them. If you do pass a pointer to a structure, you can leave any element of this structure `NULL` to use the default for that element. Here are the fields of this structure:

```
seobject scopestart;  
seobject scopeend;
```

The scope chain is how ScriptEase determines what a variable name is referring to. The scope chain is a list of objects. For a typical function, the list contains the activation object in which local variables are stored and the global object in which global variables are stored. The variables themselves are members of the object they are a part of. As a result, for a typical function, the local variables are searched first to try to resolve a variable name followed by the global variables. You can specify your own objects to be added to the list.

The `scopestart` and `scopeend` parameters are objects created using the `seMakeStack` API call. The members of these objects should themselves be objects to be added to the scope chain. In other words, `SE_INDEX(0)` should be the first object to be added to the scope chain, `SE_INDEX(1)` will be the second,

and so forth. These objects are added at the start or end of the scope chain respectively. Those added at `scopestart` are searched first during script execution.

Note that during execution the scope object is searched from the highest index to the lowest. For example, if you provide a `scopestart` object with 3 members and a `scopeend` object with 2 parameters, when `scopig` a variables objects will be searched in this order

```
scopestart[2] -- this object searched first
scopestart[1]
scopestart[0]
.. inherited globals ..
this object if implicit this
this.__parent__ chain if implicit parents
activation object
scopeend[1]
scopeend[0] -- this object will be searched last
```

Adding objects to the start of the scope chain is analogous to a script execution inside a `with` statement. A `with` statement adds a single object to the start of the scope chain. `scopestart` allows you to add a list of objects, but the same principle applies. `scopeend` works similarly but adds objects to be searched after all other places to search for a variable name.

```
seobject global;
```

Indicates a new global variable to evaluate the script using.

```
seobject default_this;
```

The `default_this` parameter allows you to determine which object will be the `this` variable for the executed script or function. For a script, the `NULL` value is traditionally used which makes the global variable the default `this` for the evaluated script as well. For a function, if the function is being invoked as a member of some object, that object should be passed as the `default_this` variable instead.

```
seobject security_init;
seobject security_term;
seobject security_guard;
seobject security_object;
```

These are the standard security functions as described in the ScriptEase language manual chapter on security. These objects work exactly the same in the ScriptEase ISDK as they do for any other ScriptEase security application.

```
seconstcharptr filename;
uint line_num;
```

These parameters are used when the `SE_TEXT` form of script is executed. They specify the virtual filename and starting line number for the script text. This is helpful in reporting errors that might occur in the script text.

---

## FUNCTION GLOBALS

One ScriptEase feature that you should keep in mind is that all functions remember the global object in effect when they are created and use that as their own global object when called. A script file, especially header files, may be self-contained packages that add functions and variables to the global object in initialization. Those functions cannot work if they are run under a different global object, they need their global object in which their definitions are stored. Therefore, specifying a different global object for a function to run under has no effect, because it is changed back when the function is actually run. If you'd like to turn off this behavior, you can use define:

```
#define JSE_MULTIPLE_GLOBAL 0
```

in your `jseopt.h` file. Be warned, doing so may make script function libraries written by other people incompatible with your application.

---

## SCOPING

A topic that leads to much confusion is that of scoping, and how to control it. Scoping is the process of resolving a variable name when it is encountered in a script. Normally, local variables are searched for the given variable name, if any, followed by global variables. The JavaScript `with` statement is the most common way to alter scoping. The various scoping rules and issues will now be examined.

### SCOPING - GLOBAL CODE

Global code is code outside of any function. Scoping for global code is simple, only the global object is searched for variables. Modifying the scoping of global code is done in the `seEval` call used to invoke that code using the `scopestart` and `scopeend` fields of the eval parameters as described above. The script user can then modify the scoping by using the `with` statement.

### SCOPING - FUNCTIONS

Functions are more complex. The normal behavior for a function is to search its local variables and parameters first. Next, the local variables and parameters of its parent function are searched. This only applies if the function is nested inside a parent function. All parents are searched if the function is nested several levels deep. Finally, the global variables are searched. Again, the user can modify this behavior using the `with` statement.

There are several methods for controlling the scope of functions. If you call the function directly using `seEval`, you can specify additions to the scope chain using the `scopestart` and `scopeend` members of the eval parameters structure. This method is rarely used because functions are usually called from within a script.

The second method is to use the `SE_IMPLICIT_THIS` and `SE_IMPLICIT_PARENTS` attributes. A script function can be given these attributes using the `seSetAttribs` API call. Both of these attributes modify the function's scope chain by adding elements to the scope chain after the local variables but before the global variables. The `SE_IMPLICIT_THIS` flag makes the function add its `this` object to the scope chain. This makes the function behave much like a C++ function in that members of the `this` object can be

referred to directly without having to qualify them with `this.` as is normal for JavaScript. `SE_IMPLICIT_PARENTS` is similar, except the parents of the `this` variable are added to the scope chain. Parents are linked through the `__parent__` (two underscores on each side) member. `this.__parent__` is the parent of the `this` variable and is added to the scope chain if `SE_IMPLICIT_PARENTS` attribute is set in the called function. Next, the parent of that object is added and so forth for all parents in the chain. This is most useful for implementing browser behavior, notably event handlers. The parents of an event handler, the element it belongs to, the document it is in, and the window it is part of, are all implicitly added in this fashion.

---

## CONTINUE FUNCTION

The `continue` function is provided to allow an API application to process code while a script is being executed. One use of it is to implement a debugger. A second use is to process Windows messages. This section pulls all the information about the `continue` function into one place.

The function is provided by the API user in the `seContextParams` structure provided to the `seCreateContext` API call. During `seEval` script evaluation, the function is called after each statement in the script is processed. However, the `seEval` call can be provided with the `SE_INFREQUENT_CONT` flag to call the function far less often. This flag is useful when code must be processed occasionally but not nearly as frequently as after each statement. Because debuggers must regain control after each statement, the `seContextParams` has a flag `SE_OPT_DEBUGGER`. This flag overrides the `SE_INFREQUENT_CONT` flag. This allows the API user to use the `SE_INFREQUENT_CONT` flag whenever it makes sense. A debugger can then optionally be used on the same code correctly, without changing that code.

Finally, when using the `SE_START` flag with `seEval` to execute code one piece at a time, control is automatically returned from the `seExec` API call after each script chunk. The amount of code executed in each call to `seExec` is determined by the presence or absence of the `SE_INFREQUENT_CONT` flag and the `SE_OPT_DEBUGGER` flag. Since control is returned to the caller after each `seExec` call, the `continue` function is not called in this case. However, you may wish to call it yourself, depending on your application.

# Wrapper functions

Wrapper functions are script functions that are written in C using the ScriptEase API instead of being written in JavaScript. From the script's point of view, they appear just like any other function and can be called identically. Most wrapper functions are initialized by the application before running scripts so as to be available to the script user right from the start. This is done by writing a wrapper function table and adding it to your `secontext` using the `seAddLibTable` ScriptEase API call. The table is added before the application makes any calls to the `seEval` ScriptEase API call. All of the standard ECMAScript objects, such as `String`, `Math`, or `Number`, are written using wrapper functions and wrapper function tables, so you have a large body of example wrapper functions included with ScriptEase to look at.

Here is a sample wrapper function, to get an idea of how one looks. The rest of this chapter is devoted to demystifying it:

```
SE_CALLBACK( void )
print(secontext se,sememcount argc)
{
    switch( seGetType(se,SE_ARGS,SE_INDEX(0)) )
    {
        case SE_TYPE_NUMBER:
            /* for whatever reason, need a specific number
             * format
             */
            printf("%0.20g",seGetNumber(se,SE_ARGS,SE_INDEX(0)));
            break;

        default:
            /* Oh what the heck, just let ScriptEase convert
             * whatever it is to a String.
             */
            printf("%s",seGetString(se,SE_ARGS,SE_INDEX(0)));
            break;
    }
    /* let's return something because we can */
    sePutString(se,SE_RETURN,SE_VALUE,
               "Go away, you bother me kid.",SE_PS_STRLEN);
}
```

Before looking into the wrapper function tables, a basic overview of a wrapper function is necessary. The example above is simple but it demonstrates all that a wrapper function does. It gets its arguments, uses them to perform the body of the wrapper function, and returns a result.

---

## THE FUNCTION HEADER

Starting with the definition of the function, notice that the return value is `SE_CALLBACK( void )`. The wrapper function returns a `void` result because it uses the ScriptEase API functions to indicate its return value which will of course be some ScriptEase value. Therefore, the C return value is not used for a wrapper function. The `SE_CALLBACK` macro takes as its parameter a C type, `void`. The macro itself is used to define functions that will be called from the ScriptEase engine rather than from your code. Some systems have special requirements to be

able to do this, and the `SE_CALLBACK` macro fills those requirements for your system.

Wrapper functions are usually called during an `seEval` ScriptEase API function call. `seEval` evaluates a script, and if that script invokes any of your functions that are implemented via a wrapper function, that wrapper function will be called by ScriptEase. Wrapper functions receives two parameters. The first is the `secontext` that is doing the callback. A wrapper function can be added to several contexts, and it needs to know which one is doing the callback. You should use this provided context in any calls to ScriptEase API functions inside your wrapper function. You can compare the returned pointer against any you might have to determine which context is being called back, but doing so is frowned upon. It is better to store any needed data along with each context using the `SE_SERVICES` object and retrieve it in your wrapper function. The second argument is simply a numeric count of the number of ScriptEase parameters passed to your function. ScriptEase wrapper functions can take varying number of arguments depending on how you define them as we will see later. If your wrapper function takes a fixed number of arguments, you can ignore this parameter.

---

## THE ARGUMENTS

To access the arguments to your wrapper function, you use any of the ScriptEase API's retrieval functions such as `seGetNumber`, `seGetString`, and so forth. These functions will automatically convert the value to the correct type if it is not of that type already. You can use `seGetType` to check the type first if you wish to be more stringent. The object/member pair to use for your arguments is `SE_ARGS`, `SE_NUM(x)` where `x` is the argument number. You can also use `SE_INDEX(x)`, as for arguments it is synonymous. Arguments range from 0 to one less than the number of arguments. `SE_ARGS`, `SE_NUM(0)` is the first argument.

---

## THE RETURN

You return a value by using the standard ScriptEase API calls `sePutNumber`, `sePutString`, and so forth. The object/member pair to put to is `SE_RETURN`, `SE_VALUE`. See "[SE\\_RETURN EXPLAINED](#)" for a thorough discussion of using `SE_RETURN`. For the simple case, you just put a value to `SE_RETURN`, `SE_VALUE`. For instance, your wrapper function could return the number 10 via:

```
sePutNumber(se, SE_RETURN, SE_VALUE, 10);
```

If you return nothing, by default the undefined value is returned. For constructor functions, the pre-constructed object is returned in this case.

---

## WRAPPER TABLES

The basic idea behind a wrapper table is that it is a list of wrapper functions to be made available to your scripts. However, wrapper tables have additional capabilities as well. You can define entire object classes using these tables.

Here is a sample wrapper table that includes many of the options that can be used.

```

SE_BEGIN_LIB_TABLE( my_lib )

    SE_NUMLITERAL( UNISTR("Identification"), UNISTR("1.03"),
                  SE_DONTENUM )
    SE_STRING( UNISTR("IdentString"), UNISTR("Version 1.03b"),
              SE_DONTENUM )

    /* Move into "Clib" */
    SE_INOBJECT( UNISTR("Clib"), SE_DONTENUM )

        /* SE_METHOD is a synonym for SE_FUNCTION */
        SE_FUNCTION( UNISTR("MyFuncCall"), MyFuncCallWrapper,
                   0, 10, SE_SECURE|SE_BYREF, SE_READONLY )

        SE_CLASS( UNISTR("MyDate"), MyDateWrapper, 0,1,
                 SE_INSECURE, SE_STOCK_ATTRIBUTES )
        /* Stock attributes are DontDelete, ReadOnly,
         * and DontEnum
         */
        SE_PROTO
            SE_FUNCTION( UNISTR("valueOf"), MyDateValueOfWrapper,
                       0, 0, SE_SECURE, SE_STOCK_ATTRIBUTES )
        SE_END_PROTO
    SE_END_CLASS

SE_END_OBJECT

/* And why not some stuff in "SElib", note that 'INOBJECT'
 * is always relative to the global object
 */
SE_INOBJECT( UNISTR("SElib"), SE_STOCK_ATTRIBUTES )
    SE_FUNCTION( UNISTR("Version"), MyVersionWrapper,
               0,0, SE_SECURE, SE_STOCK_ATTRIBUTES )

SE_END_OBJECT

/* And demonstrate the last two functions. First we make
 * 'MyLib' a copy of 'Clib'. Then we change the attributes
 * on an existing variable.
 */
SE_COPY( UNISTR("MyLib"), UNISTR("Clib"), SE_READONLY )
SE_ATTRIB( UNISTR("varname"), SE_READONLY | SE_DONTDELETE )

SE_END_LIB_TABLE

```

As you can see, the table is a list of elements where each element is one of a number of macros such as `SE_FUNCTION` or `SE_CLASS`. We will list each individual macro and what it does below. Note that the elements are not separated by commas. The whole table is begun with `SE_BEGIN_LIB_TABLE` macro and ended with the `SE_END_LIB_TABLE` macro.

First, some overview. Most macros define something and use a name as the first parameter. For instance, the first element defines a number:

```

SE_NUMLITERAL( UNISTR("Identification"), UNISTR("1.03"),
              SE_DONTENUM )

```

The name parameter follows identical rules for all of the different macros. First, when using string literals, encase them in the `UNISTR()` macro to ensure compatibility with all ScriptEase builds. When the table is added, these definitions in the macro table are created in the global object. Recall, members of the global object are the global variables of the script. This line therefore declares a new global variable named `Identification`. As the table is parsed, however, certain entries will cause this base object to change from the global object to some other object. This line is such an entry.

```
SE_INOBJECT( UNISTR("Clib"), SE_DONTENUM )
```

First, it too has a name `Clib`. Like all other names, it follows the same rules, so it refers to the `Clib` member of the global object. However, the purpose of the line is to make the named member the new base. Therefore, new names declared after this line are no longer relative to the global object, but rather to the `Clib` member of the global object. A few lines later, the `SE_END_OBJECT` macro undoes this, reverting back. This scheme allows a more readable table. It is a simple hierarchical scheme that matches well with the way objects and classes are defined.

There are two conveniences implemented. First, if you specify a name preceded by `global.`, for instance `global.foo`, the `global.` means that `foo` is relative to the global variable and the base is ignored for this entry only. Second, you can use object notation such as `foo.goo`. For instance, instead of writing:

```
SE_INOBJECT( UNISTR("Clib"), SE_DONTENUM )
SE_INTEGER( UNISTR("foo"), 10, SE_DONTENUM )
```

You could instead write:

```
SE_INTEGER( UNISTR("Clib.foo"), 10, SE_DONTENUM )
```

When using this notation, the base for further statements is not changed. The `Clib.` part of it applies only to this particular definition. Also, if the object referred to, in this case `Clib`, does not already exist or is not an object, it is converted to an object.

Choose the notation in a particular instance that is clearer. If you are going to define more than one item in an object, it is clearer to move into that object using `SE_INOBJECT` while a single item can be clearer to write out a dot-separated name.

---

## WRAPPER MACROS

What follows is a description of each macro you can use in a wrapper table and what each does.

---

SYNTAX:	<code>SE_BEGIN_LIB_TABLE( name )</code>
DESCRIPTION:	All wrapper tables are started with this macro. It specifies the name of the table. Use the table name in your call to <code>seAddLibTable</code> to add the wrapper table to your context.

---

SYNTAX:	<code>SE_INITFUNC( func )</code>
DESCRIPTION:	Specify a function to be called whenever the table is initialized.

---

---

The function's type must be:

```
typedef SE_CALLBACK(void *)
(*seLibraryInitFunc)(secontext se,void *userdata);
```

The initial data you pass in to `seAddLibTable` (as its final parameter) is passed to the initialization function. That initialization function in turn returns the userdata for the particular instance of the library table. It could just return the userdata to use the same data for all instances. If there is no initialization function, the supplied data is used directly in all instances of the library.

Note that the library can be initialized more than once, and you must be prepared to handle that case. The first time the library is initialized is when you call `seAddLibTable`, but the library will be reinitialized in certain circumstances.

---

**SYNTAX:** `SE_TERMFUNC( func )`  
**DESCRIPTION:** The companion to the initialization function, the term function looks like:

```
typedef SE_CALLBACK(void)
*seLibraryTermFunc)(secontext se,void *userdata);
```

When the library terminates, it passes its instance (not the original instance) of the userdata, the value returned from the initialization function. For each call to the initialization function, there will be one call to the termination function.

---

**SYNTAX:** `SE_NUMLITERAL( name , string , vflags )`  
**DESCRIPTION:** Create a variable in the current base object with the given name and the given value. The string passed must be parsable as a floating point number. The flags of the variable are set to the `vflags` value. The allowable flags are:

`SE_DEFAULT` No special attributes

`SE_READONLY` The member is read-only and cannot be modified.

`SE_DONTENUM` The member should not be enumerated when a script uses `for..in`.

`SE_DONTDELETE` The member cannot be deleted using the JavaScript `delete` operator.

---

**SYNTAX:** `SE_INTEGER( name , number , vflags )`  
**DESCRIPTION:** Create a variable in the current base object with the given name and the given value. Identical to `SE_NUMLITERAL`, except an integer value is given.

---

SYNTAX:	<code>SE_STRING(name, string, vflags)</code>
DESCRIPTION:	Very similar to <code>SE_NUMLITERAL</code> , except the variable is set to a string value.
SYNTAX:	<code>SE_INOBJECT(name, vflags)</code>
DESCRIPTION:	The given name is treated as an object, and if the name is not currently an object, it is turned into one. The object has its flags set to the <code>vflags</code> value. Finally, that object is the new base for all names until an <code>SE_END_OBJECT</code> is found.
SYNTAX:	<code>SE_END_OBJECT</code>
DESCRIPTION:	Undoes the <code>SE_INOBJECT</code> above so all names are derived from the base before the <code>SE_INOBJECT</code> took effect.
SYNTAX:	<code>SE_FUNCTION(name, func, min_args, max_args, func_flags, var_flags)</code>
DESCRIPTION:	<p>Declares a wrapper function. The parameters are the function's name, the function itself (a wrapper function), the minimum and maximum number of arguments, the function flags, and the variable flags.</p> <p>The maximum number of arguments can be <code>-1</code> to specify no limit.</p> <p>The function flags are one or more from the following:</p> <p><code>SE_DEFAULT</code> No special flags.</p> <p><code>SE_DYNAUNDEF</code> The object's dynamic callbacks are only called if the object does not already have the member in its internal storage, or if that member is <code>SE_TYPE_UNDEFINED</code>. (See "<a href="#">DYNAMIC OBJECTS</a>" for a complete description of callbacks.)</p> <p><code>SE_BYREF</code> Parameters passed to this function are passed by reference, so that any changes to them are reflected in the variables passed as the parameters.</p> <p><code>SE_SECURE</code> The function is secure. Only mark a wrapper function as secure if it can not perform any dangerous task. When in doubt, do not make it secure. The general rule is that any access to the system, such as reading a file or calling a system function, makes a function insecure.</p> <p><code>SE_KEEP_GLOBAL</code> Normally when a function is executed, the global object in effect when the function was created is used as the global object when the function is executed. With this flag, the current global object is retained whenever the function is executed.</p>
SYNTAX:	<code>SE_METHOD(name, func, min_args, max_args, func_flags, var_flags)</code>

DESCRIPTION:	This is a synonym for SE_FUNCTION.
SYNTAX:	SE_CLASS(name, func, min_args, max_args, func_flags, var_flags)
DESCRIPTION:	<p>This works similarly to SE_FUNCTION in that it adds the given entry as a function. However, as a class, such a function is expected to be used as a constructor. Several additional items are therefore created to facilitate this. First, the function is given a prototype which has the attributes SE_STOCK_ATTRIBS. Second, the prototype is given an _class member with a name equal to the name of the class. Finally, the prototype also gets a constructor member which points back to the class. All of these items are standard for ECMA classes.</p> <p>After this table entry is finished, the base is moved to the class object so you can add members or use SE_PROTO to add prototype members. This works in the same way SE_INOBJECT works. Use SE_END_CLASS to move back out of the object.</p>
SYNTAX:	SE_END_CLASS
DESCRIPTION:	Changes the base to its value before the SE_CLASS entry.
SYNTAX:	SE_PROTO
DESCRIPTION:	<p>Changes the base to the prototype of the current object. This is used to define the methods available to members of the current class. It is identical to:</p> <pre>SE_INOBJECT (UNISTR("prototype")) .</pre>
SYNTAX:	SE_END_PROTO
DESCRIPTION:	Changes the base to its value before the SE_PROTO entry.
SYNTAX:	SE_COPY(name, source, var_flags)
DESCRIPTION:	Acts as an assignment, copying the source value to the given name. It sets the destination flags as well.
SYNTAX:	SE_ATTRIB(name, var_flags)
DESCRIPTION:	Sets the variable flags on a given name, changing nothing else about it.
SYNTAX:	SE_END_LIB_TABLE
DESCRIPTION:	This must be the last entry in a wrapper table.

# Lifetimes

Many ScriptEase API calls such as `seGetString`, `seGetBuffer`, `seGetObject`, and `seMakeObject` return handles to a ScriptEase items. These handles remain valid for a specific amount of time, the handle's lifetime. In the API manual chapter in the descriptions of these functions, they are said to follow the standard ScriptEase lifetime model. That model is what is described in this chapter. We will use an `seobject` handle as an example for this chapter, but the other handles follow the same rules.

The critical concept to understand is the difference between the object itself and the handle to the object. The handle is what is returned to you when you call the API functions that follow the ScriptEase lifetime model. A handle is simply a way to refer to the underlying object. There are several API functions that control the lifetime of the handle. These functions allow you to control how long the handle will be valid. As long as the handle is valid, you can use it to refer to the object it represents in the many ScriptEase API calls that take an object as a parameter. This chapter describes the rules about how long a handle is valid and the API functions that determine this length.

The point to remember is that a handle is not the object itself but a way to refer to the object. When the handle becomes invalid, you may no longer use that handle to refer to the object. However, that does not mean the object itself will be deleted. The object is completely under the control of the ScriptEase runtime system which will delete the object when it determines that the object is no longer needed. It is quite possible that any particular object you have a handle to is also being used by some other part of the runtime system. When you delete your handle to the object, do not assume that the object will then be immediately freed. It may be but more likely the object will be retained because it is still being used elsewhere. There is no way to force any actual object on the system to be deleted.

The handles to objects and other items follow a simple set of lifetime rules. As long as the handle is valid, you may use it in any ScriptEase API call that requires an object. All handles are by default valid from the time they are returned to you from a ScriptEase API call until the current callback function you are in returns. All callback functions in ScriptEase are easily identified by having their return value enclosed in `SE_CALLBACK`. Common callback functions include those in the `seContextParams` structure, wrapper functions, and dynamic object functions.

This rule facilitates simple callback functions. Since the handle is automatically freed when the callback function returns, you do not have to explicitly free the handle. It is analogous to a C local variable to your callback function. Here is a valid sample wrapper function that uses an object handle:

```
SE_CALLBACK( void )
foo(secontext se, sememcount argc)
{
    seobject myobj = seMakeObject(se);
    sePutObject(se, SE_RETURN, SE_VALUE, myobj);
}
```

```
}
```

The purpose of this wrapper should be obvious, it creates and returns a new blank object. Here is an example of an invalid wrapper function:

```
static seobject myobj = NULL;

SE_CALLBACK( void )
foo(secontext se,sememcount argc)
{
    if( myobj==NULL )
    {
        myobj = seMakeObject(se);
    }

    sePutObject(se, SE_RETURN,SE_VALUE, myobj);
}
```

The intent is clear, to create a new object and return it then keep returning that same object for any further calls to the function. But, the handle returned by `seMakeObject` is only valid until the end of the wrapper function so when the wrapper function returns the first time, `myobj` comes invalid. Trying to use that handle in later invocations will use it after it has become invalid and obviously not work. We will see how to make this example work as intended shortly.

The careful reader will be wondering what happens if you get a handle when not inside a callback function. Keeping with the C analogy, handles retrieved in a callback function are local variables and handles retrieved not in a callback function are global variables. Just as global variables last the life of a program so do handles retrieved while not in a callback function. The handle is permanent and lasts until the `secontext` is destroyed and all variables and objects in it are freed.

While you may sometimes want to use a handle for your entire program, often you want to manipulate an object for a few lines of code and then be done with it. Eventually, when everyone else is done using the object, you'd like it to be freed. If you allow the handle to stay valid, you keep the object locked and it can never be freed. It will continue to use up memory until your program is done. For this reason, you may use the `seFreeXXX` API routines, `seFreeObject` in this case because we have been using `seobjects` in our discussion. `seFreeObject` tells ScriptEase that you are done using the object at that point and that your handle is to be freed then. Remember, this does not destroy the object. It only tells ScriptEase that you are no longer using the handle. As was emphasized before, ScriptEase will actually destroy the object some time in the future when it determines it is safe to do so.

To summarize the rules so far, a handle retrieved inside a callback function lasts until the handle is explicitly freed or the callback function returns, whichever comes first. A handle retrieved outside a callback function lasts until the handle is explicitly freed or the ScriptEase context is destroyed, whichever comes first.

An issue related to object lifetimes was brought up in the second wrapper function described above. How do we keep an object handle past the wrapper function it was created in? Using the C analogy, we want to turn a local variable into a global variable in the same way that the C keyword `static` does. The answer is that you use the `seLockXXX` API calls, in this case `seLockObject`.

This call indicates that the given object handle is to be valid for the life of the program. Once you pass an `seobject` to this routine, it will be treated exactly like a handle returned outside of a callback function: it lasts until the handle is explicitly freed or the ScriptEase context is destroyed, whichever comes first. If a handle already is a global handle, `seLockObject` has no additional effect.

So, the second wrapper function written correctly is:

```
static seobject myobj = NULL;

SE_CALLBACK( void )
foo(secontext se,sememcount argc)
{
    if( myobj==NULL )
    {
        myobj = seMakeObject(se);
        seLockObject(se,myobj);

        /* make the lock permanent
         * so we can keep using it
         * in every call to this
         * wrapper function.
         */
    }

    sePutObject(se, SE_RETURN,SE_VALUE, myobj);
}
```

You will notice the `seCloneXXX` API calls such as `seCloneObject`. These calls take a handle, which follows the rules just described, and makes a second handle identical to the first. If the first handle was to be freed at the end of the current callback function, the clone will be freed then as well. Once created, you have two independent handles with different pointer values although they both refer to the same ScriptEase object. They both follow the lifetime rules given above independently. For instance, you might clone a regular local handle and pass it to a utility routine. You continue to use the original handle until it goes away at the end of the wrapper function. The utility routine may call `seLockObject` on the cloned handle and use it for a while. That is perfectly valid, both handle are independent.

# Objects and Classes

One of the most important tasks for a ScriptEase application writer is to design and implement object classes for the application's scripts to use. Most applications will have underlying data and functions that the script should be able to access in object form. This chapter will start with a discussion of object classes and finish with details on implementing those classes using ScriptEase.

---

## OBJECT CLASSES

An object class starts with a constructor function. A constructor function's job is to initialize a new object of the object class. It can be written in C using wrapper functions or implemented in JavaScript. When the user wishes to create a new object of your class, he calls your constructor function using the new operator such as:

```
var a = new MyClass();
```

In this case, the constructor function is `MyClass`. Your constructor function will have a new blank object of its class provided to it as its `this` variable. The function can then add members to the `this` variable as appropriate for the task your object class is designed to perform. Here is a simple circle class constructor written in JavaScript:

```
function circle(radius)
{
    this.radius = radius;
}
```

With this constructor in your script, you can create a new circle object in JavaScript such as `new circle(10)`. Although this example has implemented the circle constructor in JavaScript, you could also implement the circle constructor using the ScriptEase API as we will demonstrate later in this chapter.

The particular parameters you pass to your constructor as well as how you set up your new object are determined by the object's intended use. The main point to remember is that the `this` variable passed to your constructor is already a blank object of the constructor's object class. All objects of a single class share common members via their `prototype`. This sharing is set up for the pre-made `this` variable passed to your constructor.

You designate the methods to share by putting them in the `prototype` member of the constructor function. All object's of the constructor's class have access to those members. Here is a simple script that uses a slightly extended version of the `circle` constructor:

```
function circle(radius)
{
    this.radius = radius;
}

function circle.prototype.toString()
{
    return "circle of radius " + this.radius;
}
```

```
var a = new circle(5);
Clib.puts(a.toString());
```

This is a simple program that will print `circle of radius 5`. Although we've implemented this in script form, you can do the same using the ScriptEase API. Here is the version that does so:

```
SE_CALLBACK( void )
circle(secontext se,sememcount argc)
{
    assert( argc==1 );
    seAssign(se, SE_THIS,SE_MEM("radius"), SE_ARGS,SE_NUM(0));
}
SE_CALLBACK( void )
circleToString(secontext se,sememcount argc)
{
    sechar buffer[128];

    sprintf_sechar(buffer,UNISTR("circle of radius %d"),
                    (int)seGetNumber(se,SE_THIS,SE_MEM("radius")));
    sePutString(se, SE_RETURN,SE_VALUE, buffer, SE_PS_STRLEN);
}

SE_BEGIN_LIB_TABLE( circleTable )
SE_CLASS( "circle", circle, 1, 1, SE_SECURE, SE_DEFAULT)
SE_PROTO
SE_METHOD( "toString", circleToString, 0, 0, SE_SECURE,
           SE_DEFAULT)
SE_END_PROTO
SE_END_CLASS
SE_END_TABLE

. . .

seAddLibTable(se,circleTable,NULL);
```

Notice that the `circle` function in both the JavaScript and ScriptEase API versions returns no value. It instead initializes the provided `this` variable. Constructors can return a value which will override the default preconstructed `this` variable. However, doing so requires you to do all of the initialization for the object you intend to return yourself.

Please refer to a JavaScript language book for more information on objects and object classes.

---

## DYNAMIC OBJECTS

We've seen how to make class objects constructors and prototype functions. However, it is often desirable to produce objects that are more flexible than a standard object. You may want to map an object to a real entity in your application and have changes to it immediately reflected. For instance, you might want to map an object to your display screen such that when a user writes:

```
displayObj.background = BLUE;
```

Your screen changes to the color blue. You do this using dynamic objects. While dynamic objects are most often used to make flexible class members, any object can be dynamic not just members of a class.

Very often you will want to associate one or more C or C++ pointer directly with your object, so that when your wrapper function retrieve that object that can also retrieve the C/C++ pointer. Using `seGetPointer()` and `sePutPointer()` along with `SE_HIDDEN_MEM` or `SE_HIDDEN_UNIMEM` or with an `seInternalizeStringHidden` property, is an excellent way to keep the data on your C/C++ side safe from the script code and always associated with the proper objects.

ScriptEase allows you to implement a table of callback functions that you associate with your object using the `seSetCallbacks` API function. Normally you do this in your constructor when initializing an object of your class. This table has callbacks for all the object manipulation tasks such as getting a member, putting a value to a member, deleting a member, etc.

Your callbacks will override the normal behavior for the object. To implement the above example, you would override the `put` behavior of the `displayObj` object. Your code would check for your special property `background` and changing the screen color to match the color being put to that member. You can override only some of the behaviors by leaving the others you are not interested in as `NULL` in the table.

Here is a list of the functions in the table. The function prototypes are given for the various functions, when they are called, and what their parameters and return mean. When implementing any of these functions for your own object, remember that `SE_THIS` refers to the object being manipulated.

---

```
SE_CALLBACK( sebool )
get(secontext se, sestring prop, sebool call_hint);
```

The `get` callback is used when a member's value is being accessed. It is also used when trying to determine if an object has a property if you have not declared `hasProp` (see below). Declaring `hasProp` is the preferred method.

The `prop` parameter, a parameter to most of these dynamic callback functions, indicates which member of the `SE_THIS` object is to be accessed. Normally, you use `seInternalizeString` at the beginning of your program to internalize your special properties, then you can compare them with the property being accessed using a single pointer comparison. The alternative is to turn `prop` into a string using `seGetInternalString` then compare with a `strcmp_sechar`, but this is a lot of work and must be done on each get operation.

`call_hint` is a boolean indicating if ScriptEase believes the returned value is going to be used as a function to call. This would be the difference between:

```
a = yourobj.foo; /* call_hint==FALSE */
```

and

```
a = yourobj.foo(); /* call_hint==TRUE */
```

Knowing this information is useful in certain dynamic objects in which a property and a method require different setup routines, such as COM.

Once you've decided what value the dynamic property should have, you return it using the usual `SE_RETURN` object and return `TRUE` from the function. If you've decided the property is not one you are interested in, return `FALSE`. `ScriptEase` will act just as if the dynamic callback did not exist in this case, looking up the property in its internal storage for the object.

Note that you can access the internal storage of the object within your dynamic callback implementation. You should use the `Direct` versions of the `seGetXXX` and `sePutXXX` API calls in order to bypass your dynamic properties. If you use the non-`Direct` versions, the internal storage will be used for your object but only for gets. This is because a particular callback for an object is shut off inside that callback, to prevent infinite recursion. However, only that one callback is shut off. If you use the object in a way that uses another callback, `ScriptEase` will use that callback. On rare occasions, you want that behavior. Most of the time, however, the implementation of a dynamic callback will want to directly access the members of its object. It is usually much clearer and quicker to just use the `Direct` versions of all `ScriptEase` API calls while implementing a dynamic callback.

---

```
SE_CALLBACK( sebool )
put(secontext se, sestring prop);
```

This callback is used whenever any of the object's members is being put to. Like the `get` callback, the parameter `prop` indicates the property being updated. The value being put to that property is the first (and only) parameter to the callback, `SE_ARGS, SE_NUM(0)`. Also like `get`, you return `TRUE` if you've handled the put operation and `FALSE` if you still want `ScriptEase` to update its internal storage for the object in the regular way.

Like the other dynamic callbacks, the `put` callback for your object is turned off while inside of it. However, it is usually better to make this behavior irrelevant by always using the `Direct` versions of the `ScriptEase` API calls inside a dynamic callback.

---

```
SE_CALLBACK( int )
hasProp(secontext se, sestring prop);
```

This callback is used when searching for a variable. `ScriptEase` maintains an internal list of objects to search when resolving a variable reference. This list is called the scope chain and is described fully in the Execution chapter. This list usually consists of the Activation Object, where local variables are stored, followed by the Global Object. It is easy to add objects to the list by using the `with` statement. If your object is on this list, this callback will be used to determine if your object contains any property being searched for.

The return value can one of the following:

```
HP_HAS
```

The object has the property.

```
HP_HASNOT
```

The object does not have the property.

```
HP_CHECK
```

Disregard this callback and check in the normal way. The normal way involves calling your dynamic `get` callback if you have one.

```
HP_DIRECTCHECK
```

Disregard this callback and check for the property in the object's internal storage only, do not call the `get` callback.

---

```
SE_CALLBACK( sebool )
canPut(secontext se,sestring prop);
```

Before trying to put a value, `canPut` will be called to determine if it is to be allowed. You determine whether or not a property can be updated with this callback. Return `TRUE` to allow the put. Implementing this callback is most useful if you are not implementing a `put` callback, because if you are then you can merge the functionality of this callback into the `put` callback by simply not doing any updating.

---

```
SE_CALLBACK( sebool )
deleteProp(secontext se,sestring prop);
```

When a property of an object is to be deleted, this callback will be invoked. As usual, return `FALSE` if you want ScriptEase to delete the property from its internal storage. This routine will also be called when the object itself is to be deleted, a destructor. In this case, the `prop` parameter will be `SE_NO_VARNAME`.

---

```
SE_CALLBACK( void )
defaultValue(secontext se,seDataType hint);
```

When an object is used in a situation when it has to be converted to a primitive value (i.e. a string or number), this callback is used to do so. The only parameter is `hint`, the type that the system needs the value as. It is permissible to always convert to a single primitive type, which will then itself be converted to the correct value, if you don't want to take the hint into account. Return the value in the `SE_RETURN` object.

---

```
SE_CALLBACK( sebool )
```

```
operatorOverload(secontext se, sword16 op);
```

ScriptEase implements operator overloading. Whenever an object is used as the left-hand operand, this callback is invoked. The `op` parameter will be the operator being overloaded, according to this table:

SE_OP_PREINC	++expr
SE_OP_POSTINC	expr++
SE_OP_PREDEC	--expr
SE_OP_POSTDEC	expr--
SE_OP_ASSIGN	lhs = expr
SE_OP_NOT	!expr
SE_OP_UNARY_PLUS	+expr
SE_OP_UNARY_MINUS	-expr
SE_OP_BITNOT	~expr
SE_OP_EQUAL	expr==expr
SE_OP_NOTEQUAL	expr!=expr
SE_OP_STRICT_EQUAL	expr===expr
SE_OP_STRING_NOTEQUAL	expr!==expr
SE_OP_LESS	expr<expr
SE_OP_LESS_EQUAL	expr<=expr
SE_OP_GREATER	expr>expr
SE_OP_GREATER_EQUAL	expr>=expr
SE_OP_SUBTRACT	expr-expr
SE_OP_ADD	expr+expr
SE_OP_MULTIPLY	expr*expr
SE_OP_DIVIDE	expr/expr
SE_OP_MOD	expr%expr
SE_OP_SHIFLEFT	expr<<expr
SE_OP_SHIFTRIGHT	expr>>expr
SE_OP_USHIFTRIGHT	expr>>>expr
SE_OP_OR	expr expr
SE_OP_XOR	expr^expr
SE_OP_AND	expr&expr

The assign operators, such as `*=`, are performed as two separate operations, as if written `expr = expr * expr` instead of `expr *= expr`.

The right-hand side of the operator is to be found in `SE_ARGS`, `SE_NUM(0)`. The result of the operation should be returned in the `SE_RETURN` object with a return from the function of `TRUE`. A return of `FALSE` will do the normal operation which will involve converting the object to a primitive type compatible with the other operand and doing the JavaScript operation.

Note that the operator overload will be called with the op `SE_OP_ASSIGN` if the object is assigned to. Normally, this operation is ignored since you cannot assign to an object directly. In a script, you can write:

```
some_obj = 10;
```

but this just discards the object in the given variable and replaces it with 10. If the object has operator overloading, this will call the overload callback instead. If you return `FALSE`, the normal changing of `some_obj`'s value takes place. If you return `TRUE`, it does not. Be careful, you can make a variable whose value the user can never change in this way.

---

```
SE_CALLBACK( sebool )
getByIndex(secontext se,int index);
```

This callback is used to get an object member's value by index. This will be used solely by the ScriptEase API when a programmer is trying to iterate the members of your dynamic object. There is no hint as there is no way to know how the programmer intends to use the retrieved value. Return `FALSE` if you have no such indexed member.

In order to implement this routine correctly, you need to internally order the members of your dynamic object in a consistent way. A person will be using this routine to iterate all of your members, from 0 on up. You must return each member once only and always in the same index. It is only permissible to reorganize the members if a member is added or removed. Return the member in the `SE_RETURN` object.

---

```
SE_CALLBACK( sestring )
getNameByIndex(secontext se,int index);
```

A companion routine to `getByIndex`, this is used when a script wants to iterate through your object using the `for...in` statement. You must return the names of your object's members according to their index. Like `getByIndex` above, it is only permissible to reorder your object if a member is added or removed. Return `SE_NO_VARNAME` to indicate an index beyond the number of members in your object. Otherwise return the internalized version of your member's name (see [seInternalizeString](#)). The internalized string will be freed when you return it just as if you called `seFreeInternalString`. This is useful in the majority of cases

in which you create the name to return and no longer need it locked. If you do need to retain a lock on the returned string, use `seCloneInternalString` to make a duplicate to return.

---

```
SE_CALLBACK( sememcount )
getMaxIndex(secontext se);
```

Return the maximum index of the members of your objects which is equal to the number of members minus one.

For all of the above callbacks, the `SE_DYNA_UNDEF` flag will cause your dynamic property to be called only if the object does not contain the property in its internal storage. This is useful for speed. When your dynamic `put` callback is invoked on a property, if that property is not special, you can return `FALSE` to put it into the object's internal storage. From then on, that property will be treated normally. The properties you are interested in you do not store in the object, you handle them in your callback. They will continue to be routed through your callbacks each time they are accessed.

---

## FUNCTION REDIRECTION

Normally, an object is either a function or it is not. If it is a function, it can be invoked or used as a constructor such as by `Func()`; or `new Func()`; . Each of these behaviors can be overridden. Two special members can be added to an object to override, `_call` and `_construct`. They are used in the two instances above, `_call` when invoked as a regular function and `_construct` when used in a constructor with the `new` operator. These special members must themselves be functions that are called in the appropriate case. It is possible to turn a regular non-function object into a callable function by giving it an `_call` member and a constructable object likewise by giving it an `_construct` member.

# API Function List

Here are the API functions organized by functionality. For all the API functions, if the call has an output parameter, a pointer to something filled in by the function, you can always pass `NULL` if you don't care about that particular output.

---

## INITIALIZATION/CONTEXT CREATION

### seInitialize

---

**SYNTAX:**            `uint  
seInitialize(void);`

**WHERE:**            `None`

**RETURN:**            The ScriptEase engine's version identifier.

**DESCRIPTION:**    `seInitialize` is used to initialize the engine, once per application. See `seTerminate` for the termination. Call this at the start of your program, before doing any other ScriptEase calls. All ScriptEase applications, even multithreaded ones, should call this routine only once.

**SEE:**                [seTerminate](#)

---

### seTerminate

---

**SYNTAX:**            `void  
seTerminate(void);`

**WHERE:**            `None`

**RETURN:**            `None`

**DESCRIPTION:**    Call `seTerminate` once before your application exits to cleanup ScriptEase. You must destroy any `secontexts` created before calling this routine.

**SEE:**                [seInitialize](#)

---

### seCreateContext

---

**SYNTAX:**            `secontext  
seCreateContext(struct seContextParams *params,  
                  seconstcharptr userkey);`

**WHERE:**            `params` a pointer to an `seContextParams` structure filled in with context options.

`userkey` the userkey, if applicable

**RETURN:**            An `secontext`, suitable to be used in further ScriptEase API calls.

**DESCRIPTION:**    Create a scripting context. Chapter "[Initialization and Contexts](#)" is devoted to initializing and creating new contexts, see it for full details.

---

---

The userkey is provided to you via email when you download an evaluation version of ScriptEase. Purchased versions ignore this parameter, for which you can pass NULL.

SEE: [seDestroyContext](#)

---

## seCreateBlankContext

---

**SYNTAX:** `secontext  
seCreateBlankContext(  
 struct seContextParams *params,  
 seonstcharptr userkey);`

**WHERE:** `params` a pointer to an `seContextParams` structure filled in with context options.

`userkey` the userkey, if applicable

**RETURN:** An `secontext`, suitable to be used in further ScriptEase API calls.

**DESCRIPTION:** This routine create a scripting context without standard functions. You should use `seCreateContext` to create your scripting contexts. This function is used by `seCreateContext` to do so. If you create a scripting context using this function directly, scripts run in this context will have no standard functions available such as `eval` or any of the standard objects `String`, `Number`, etc.

The userkey is provided to you via email when you download an evaluation version of ScriptEase. Purchased versions ignore this parameter, for which you can pass NULL.

SEE: [seCreateContext](#), [seDestroyContext](#)

---

## seCreateFiber

---

**SYNTAX:** `secontext  
seCreateFiber(secontext parent);`

**WHERE:** `parent` a parent context to relate the fiber to

**RETURN:** An `secontext`, suitable to be used in further ScriptEase API calls.

**DESCRIPTION:** Create a fiber context. See chapter on [Fibers and Threads](#) for full details on the topic of multithreading and fiber contexts.

SEE: [seCreateContext](#), [seDestroyContext](#)

---

## seGetContextParams

---

**SYNTAX:** `struct seContextParams *  
seGetContextParams(secontext se);`

**WHERE:** `se` the context to get the parameters from.

**RETURN:** A pointer to the `seContextParams` structure for this context.

**DESCRIPTION:** Get a pointer to the context's parameter structure. The contents of the `seContextParams` structure used to create the context is

---

---

stored with the context. You get a pointer to it and examine or modify the parameters for the context.

SEE: [seCreateContext](#)

---

## seDestroyContext

---

SYNTAX: `void  
seDestroyContext(secontext se);`

WHERE: `se` the context to destroy

RETURN: None

DESCRIPTION: When you are done with a context, you destroy it to free up all associated resources, such as memory allocated.

SEE: [seCreateContext](#), [seCreateBlankContext](#), [seCreateFiber](#)

---

## seAddLibTable

---

SYNTAX: `sebool  
seAddLibTable(secontext se,  
                  struct seLibraryTableEntry *table,  
                  void *data);`

WHERE: `se` the context to add the functions to

`table` the table of functions to add

`data` user data for the library

RETURN: A boolean indicating success. Failure can happen on an illegal table or if memory becomes exhausted.

DESCRIPTION: This routine parses a library table and adds the variables, functions, and classes defined in it to your context. You need to add the tables to your context only once, right after you create it. From then on, all scripts run in the context will have access to the things you've defined in it. You do need to add the table to each context. You should consider consolidating all of your `seAddLibTable` calls into an `sePrepareContextFunc` callback (see [Initialization and Contexts](#)) so all contexts created in your application have access to the functions.

SEE: None

---

## seGarbageCollect

---

SYNTAX: `void  
seGarbageCollect(secontext se,int action);`

WHERE: `se` the context to collect

`action` the garbage collection action to perform

RETURN: None

DESCRIPTION: This routine allows you to manipulate and invoke garbage collection on a given context. `action` can be one of the following:

---

---

SE\_GARBAGE\_COLLECT

Perform a garbage collection immediately, even if it has been disabled.

SE\_GARBAGE\_OFF

Disable garbage collection. Instead of collecting to free up unused memory, more memory is always allocated from the system whenever existing storage is exhausted.

SE\_GARBAGE\_ON

Re-enable garbage collection.

Note that each SE\_GARBAGE\_OFF must be paired with one SE\_GARBAGE\_ON. If SE\_GARBAGE\_OFF has been invoked several times, garbage collection will not be restarted until SE\_GARBAGE\_ON has been invoked the same number of times. However, a garbage collection can always be forced using the SE\_GARBAGE\_COLLECT action.

SEE: None

---

## VARIABLE LOCATING

### seVarParse

---

SYNTAX:           sebool  
                  seVarParse(secontext se,  
                              seobject start\_object,  
                              seconstcharptr string,  
                              seobject \*object,  
                              sestring \*member,  
                              uint flags);

WHERE:            se the context to look for the variable in  
  
                  start\_object the object to start searching from  
  
                  string the string name of the variable  
  
                  object an output parameter filled in with the object  
  
                  member an output parameter filled in with the member  
  
                  flags flags to control variable resolution.

RETURN:           A boolean indicating if the variable was found.

DESCRIPTION:     Turn a text variable name into the correspond Object,member pair. Both output-only parameters, object and member, follow the usual ScriptEase lifetime rules for the returned value types. See [seGetObject](#) and [seInternalizeString](#) for more information on the object and member respectively.

This routine parses a variable name and returns the given variable's location. This allows you to read and update the variable's value. The variable name must be constant. For instance, `foo[5].goo` is acceptable but `foo[goo].goo` is not

---

---

because in this case `[goo]` would mean to access the variable `goo` as a string and use that member name. Similarly, `goo(5).zoo` is not allowed because it calls a function. The reasoning is that this routine is used to access variables by name, but it should be quick. If you need to use full-fledged expressions, you should use the `seEval` routine instead although that is much slower.

The primary return is the output parameters which are filled in with an Object,Member pair you use to access or update that variable. You would later pass the `object` and `SE_STR(member)` to any of the other API functions to manipulate that variable. These return values follow standard rules for **Lifetimes**, and so may need extra code for cleaning up if this is not called in a wrapper function. You may often choose `SE_COMPOUND_MEM` or `SE_COMPOUND_UNIMEM` along with standard `seGet` and `sePut` calls for simple access to complex representations of a single variable.

The flags may be any combination of the follows, |'ed together:

`SE_DEFAULT`

`SE_GF_COMPOUND_CREATE` - objects will be created if they don't yet exist. see **VARIABLE READING** for more information on this flag.

SEE: `seGetObject`, `seInternalizeString`

---

## seGetName

---

SYNTAX: `seconstcharptr  
seGetName(secontext se,  
          seobject object,  
          semember member,  
          sememcount *len);`

WHERE: `se` the context the name is resolved in  
`object` the object the variable is in  
`member` the member name  
`len` an output parameter, the length of the string

RETURN: The text of the variable's name

DESCRIPTION: Given an Object,Member pair, get a name for the variable This function gets the full name of the given variable. It is intended for error reporting. Be warned, this is a very slow function.

The returned string follows the usual ScriptEase lifetime rules.

SEE: None

---

## seInternalizeString

## seInternalizeStringHidden

---

SYNTAX:	<pre> sestring seInternalizeString(secontext se,                     seconstcharptr string,                     sememcount len);  sestring seInternalizeStringHidden(secontext se,                           seconstcharptr string,                           sememcount len); </pre>
WHERE:	<p><code>se</code> the context to internalize the string into</p> <p><code>string</code> the text of the member name to internalize</p> <p><code>len</code> the length in characters (not bytes) of the string, or <code>SE_IS_STRLEN</code> to let <code>seInternalizeString</code> use <code>strlen_sechar()</code> to determine the length of the string.</p>
RETURN:	The internalized <code>sestring</code>
DESCRIPTION:	<p>All object member names are internalized by the ScriptEase engine before use. This API call is used to get the internalized version of a particular string. It is useful for commonly-used strings as whenever you use the text of the string, ScriptEase must internalize that string. In addition, ScriptEase internal strings can be directly compared using a single <code>==</code> comparison rather than the much slower <code>strcmp_sechar</code>.</p> <p>The resulting <code>sestring</code> can be used as a member name using the <code>SE_STR()</code> member name specifier. In addition, object callbacks return <code>sestring</code> for the member name being accessed.</p> <p>ScriptEase internal strings are always locked until explicitly freed. Use <code>seFreeInternalString</code> to indicate you are finished with a particular internal <code>sestring</code>. You can also duplicate an <code>sestring</code> using <code>seCloneInternalString</code>. Refer to the standard ScriptEase lifetime model, as internal strings follow that with the exception that no internal strings are freed automatically when a wrapper function exits.</p> <p>The difference between <code>seInternalizeString()</code> and <code>seInternalizeStringHidden()</code> is that <code>seInternalizeStringHidden()</code> will create a property name that is not accesible from scripts (similar to <code>SE_HIDDEN_MEM</code> or <code>SE_HIDDEN_UNIMEM</code>).</p>
SEE:	<a href="#">seCloneInternalString</a> , <a href="#">seFreeInternalString</a> , <a href="#">seGetInternalString</a>

---

## seCloneInternalString

---

SYNTAX:	<pre> sestring seCloneInternalString(secontext se,                       sestring str); </pre>
WHERE:	<p><code>se</code> the context the string belongs to</p> <p><code>str</code> the internal string to clone</p>
RETURN:	A duplicate of the <code>sestring</code>
DESCRIPTION:	This is a standard clone function as described in the <a href="#">Lifetimes</a> chapter. The returned <code>sestring</code> acts as an exact duplicate of the

---

---

original `sestring`.

SEE: [seInternalizeString](#), [seInternalizeStringHidden](#),  
[seFreeInternalString](#), [seGetInternalString](#)

---

## seFreeInternalString

---

SYNTAX:               void  
                      seFreeInternalString(secontext se,  
  sestring str);

WHERE:                se the context the string belongs to

                      str the internal string to free

RETURN:               None

DESCRIPTION:        This is a standard free function as described in the [Lifetimes](#) chapter. Once called, the `sestring` is freed up and is no longer valid.

SEE:                 [seInternalizeString](#),  
                      [seInternalizeStringHidden](#),[seCloneInternalString](#),  
                      [seGetInternalString](#)

---

## seGetInternalString

---

SYNTAX:               seconstcharptr  
                      seGetInternalString(secontext se,  
  sestring str,  
  sememcount \*len);

WHERE:                se the context the string is part of

                      str the `sestring` to get the text of

                      len an output parameter filled in with the length of the string's text in characters (len may be NULL)

RETURN:               The text of the string

DESCRIPTION:        Retrieves the text of a member described by an `sestring`. The `len` parameter (if not NULL) is filled in with the length of the returned string in characters. The value returned by this call follows the same lifetime rules as [seGetString](#), and the string returned by `seGetInternalString` may in all other ways be treated as one returned by [seGetString](#).

Note: Prior to the se501a release, the value returned by this call could be stored in a temporary location and was only guaranteed to be valid until the next call into the script-engine API. This older behavior may be defining `SE_GETINTERNALSTRING_NO_LIFETIME` in your `jsopt.h` file.

```

WHERE: `se` the context to get the variable from  
`object` the object half of an Object,Member pair  
`member` the member half of an Object,Member pair

---

---

`fl` flags determining how the variable is retrieved

`len` the length of the returned data for `seGetStringEx` in characters

RETURN: The C value for the variable.

DESCRIPTION: These routines are a core element of the ScriptEase API. Given an Object,Member pair, these routines extract the current value as the given type, converting if necessary, and return the result. Note that the underlying variable does not change type, its value is retrieved and converted without changing the source variable. A valid return will always result from these functions. If an internal error occurs, like an illegal conversion, that error will be set up as the result of your function (see `seThrow`), but a valid result is still returned. The intent is that you can write a simple wrapper with no error checking that uses these routines. See the section [SE\\_RETURN EXPLAINED](#) in "[Working with Variables](#)" for a discussion of the implications of this behavior. The value returned if an error occurs will always be a stock value. For numbers, it is `SE_NAN` (or 0 for non-floating point numbers). For strings, an empty string, `UNISTR("")`, is returned. For objects, `SE_NOWHERE` is returned. Finally, for booleans `FALSE` is returned.

The flags parameter can be any of the following |'d together:

**SE\_DEFAULT**

**SE\_GF\_NOPROTOTYPE** - ignore the object's prototype when looking for the property

**SE\_GF\_NOCALLBACKS** - ignore the object's dynamic methods when looking for the property. It directly accesses the object's internal structure. It is intended for writing faster dynamic routines.

**SE\_GF\_DIRECT** - This is a bitwise OR of `SE_GF_NOPROTOTYPE` and `SE_GF_NOCALLBACKS` to ignore the object's prototype and dynamic methods when looking for the property. See the sections on [DYNAMIC OBJECTS](#) for more information on using this flag

**SE\_GF\_CALL\_HINT** - if the member is retrieved via a dynamic get callback (on [DYNAMIC OBJECTS](#) for more information about get callbacks), then this flag will set the `call_hint` value to `TRUE` for that callback.

**SE\_GF\_UNDEF\_OBJ\_OK** - if `seGetObject()` is called and the property cannot be converted to an object because it is `SE_TYPE_UNDEFINED` or `SE_TYPE_NULL`, then normally an exception will be generated because these types cannot be converted to an object. With this flag set the property will stay as it is and no exception will be generated (although your returned object will be `SE_NOWHERE`).

---

**SE\_GF\_COMPOUND\_CREATE** - This flag applies only to the `SE_COMPOUND_MEM` and `SE_COMPOUND_UNIMEM` types, or to calls to `seVarParse()`. This flag means that the variable is created so it always exists after the call even if it did not before the call. Any piece of the variable is likewise created, so if you refer to `foo.goo` and there is no variable `foo`, then `foo` is created and made an object and is given the member `goo` which will initially be of type `SE_TYPE_UNDEFINED`; but if you refer to `foo.goo.zoo` and there is no variable `foo` then `foo` and `foo.goo` are created and made objects.

In addition, you can specify the flags by using different named functions that have the flags as part of their name. In this case, you do not specify the flags, they are implicit. Taking `seGetNumberEx` as an example:

```
seGetNumber(...) = seGetNumberEx(..., SE_DEFAULT)
seGetDirectNumber(...) =
seGetNumberEx(..., SE_GF_DIRECT)
```

The return from `seGetStringEx` and `seGetObjectEx` both follow the usual ScriptEase lifetime rules described in the [Lifetimes](#) chapter.

SEE: None

---

## seFreeObject

## seFreeString

---

SYNTAX:           void  
                  seFreeObject(secontext se, seobject item);  
  
                  void  
                  seFreeString(secontext se, seconstcharptr item);

WHERE:            se the context the item is associated with  
  
                  item the item to free

RETURN:           None

DESCRIPTION:     These are the standard lifetime free routines corresponding to `seGetXXX`. See [Lifetimes](#) for the standard ScriptEase lifetime rules.

You use these functions to explicitly free an object or string returned from `seGetObjectEx` and `seGetStringEx`. Once freed, the object or string is no longer valid.

SEE:              [seGetObjectEx](#), [seGetStringEx](#)

---

## seCloneObject

## seCloneString

---

SYNTAX:           seobject

---

---

	<code>seCloneObject(secontext se,seobject item);</code>
	<code>    seconstcharptr</code>
	<code>seCloneString(secontextse,seconstcharptr item);</code>
WHERE:	<code>se</code> the context the item belongs to
	<code>item</code> the item to clone
RETURN:	The cloned item
DESCRIPTION:	The standard lifetime clone routines corresponding to <code>seGetXXX</code> . See <a href="#">Lifetimes</a> for the standard ScriptEase lifetime rules which these functions are a part of.
	These calls produce a duplicate of the item. The duplicate and the original handle refer to the same item but are independent. For instance, freeing one of the handles means that handle can no longer be used, but the other handle is still valid until it is freed.
SEE:	<a href="#">seGetObjectEx</a> , <a href="#">seGetStringEx</a>

---

## seWeakLockObject

---

SYNTAX:	<code>void</code> <code>seWeakLockObject(secontext se,seobject obj,</code> <code>                  sebool weak);</code>
WHERE:	<code>se</code> the context the object is part of
	<code>obj</code> the object to weak lock
	<code>weak</code> should the object be weak locked
RETURN:	None
DESCRIPTION:	Lock an item to produce a weak lock. Like <code>jseLockObject</code> , the handle will remain until explicitly freed. The boolean determines if the lock is weak. <code>jseLockObject</code> always produces normal locks. Therefore, this routines is usually used to produce weak locks, so the parameter is <code>TRUE</code> . On occasion, you may need to turn off an existing weak lock and restore it to a full lock which is when the parameter may be <code>FALSE</code> .
	This API function is designed to resolve a common problem. It is typical when mapping a C object to a JavaScript object for a programmer to want each item to have a reference to the other. This allows both sides to have access to its counterpart to perform any needed task. The problem that arises is that the lock on the ScriptEase object by the API keeps the object permanently in memory, even when ScriptEase is no longer using the object. It is a cyclic loop that cannot be detected because the cycle extends outside of the ScriptEase core.
	Using <a href="#">seWeakLockObject</a> , the programmer retains a handle to the object but that handle does not lock the object in memory. If ScriptEase is no longer using the object, the presence of this lock does not keep it from being garbage collected. Other than that

---

---

difference, this function performs exactly like `seLockObject`.

Be careful with this function. The object can be cleaned up at any time once the script is no longer using it. If you try to use a handle to such an object, you will probably crash the system. You should make sure to add a destructor to the object so that you know when you must stop using the handle and free the handle using `seFreeObject` at that time. Any use for this function other than this intended one is likely to crash your application.

SEE: `seLockObject`, `seFreeObject`

---

## seLockObject

## seLockString

---

SYNTAX: `void seLockObject(secontext se, seobject obj);`

WHERE: `void seLockString(secontext se, seconstcharptr str);`  
`se` the context the object is part of  
`obj` the object to lock  
`str` the string to lock

RETURN: None

DESCRIPTION: Lock an item. The item will remain locked until it is explicitly freed. `seLockObject` always produces normal locks.

SEE: `seFreeObject`, `seWeakLockObject`, `seFreeString`

---

## seGetType

---

SYNTAX: `sedatatype seGetType(secontext se, seobject object, semember member);`

WHERE: `se` the context the member is in  
`object` the Object half of an Object,Member pair  
`member` the Member half of an Object,Member pair

RETURN: The type of the member.

DESCRIPTION: This is a simple function, it returns the current type of the given variable. Members that do not exist are reported as type `SE_TYPE_UNDEFINED`. Members can also exist with type `SE_TYPE_UNDEFINED`. Use the `seExists` api call to differentiate them.

SEE: `seExists`, `seExistsDirect`

---

## seExists

---

SYNTAX: `sebool seExists(secontext se, seobject object, semember member);`

---

---

WHERE:	<p><code>se</code> the context the member is in</p> <p><code>object</code> the Object half of an Object,Member pair</p> <p><code>member</code> the Member half of an Object,Member pair</p>
RETURN:	TRUE if the member exists, else FALSE.
DESCRIPTION:	This API function is used in place of <code>seGetType</code> when you do not care what the type of the member is, only if it exists or not.
SEE:	<code>seGetType</code> , <code>seExistsDirect</code>

---

## seExistsDirect

---

SYNTAX:	<pre>sebool seExistsDirect(secontext se, seobject object,                semember member);</pre>
WHERE:	<p><code>se</code> the context the member is in</p> <p><code>object</code> the Object half of an Object,Member pair</p> <p><code>member</code> the Member half of an Object,Member pair</p>
RETURN:	TRUE if the member exists, else FALSE.
DESCRIPTION:	<p>This API function is used in place of <code>seGetType</code> when you do not care what the type of the member is, only if it exists or not. Unlike <code>seExists</code>, this function ignores any dynamic properties on the object and only checks if the internal ScriptEase storage for the object contains the given member. Like all the <code>Direct</code> functions, it is meant to be used in implementing object dynamic functions so that the dynamic functions themselves can use the internal ScriptEase store without having to take into account the possibility of being called by each other.</p>
SEE:	<code>seGetType</code> , <code>seExists</code>

---

## seGetAttribs

---

SYNTAX:	<pre>seAttributes seGetAttribs(secontext, seobject object,              semember member);</pre>
WHERE:	<p><code>se</code> the context the member is in</p> <p><code>object</code> the Object half of an Object,Member pair</p> <p><code>member</code> the Member half of an Object,Member pair</p>
RETURN:	The attributes of the member
DESCRIPTION:	<p>This function gets a member's attributes. The attributes a member has can be one or more of the following flags,  'd together:</p> <p><code>SE_DEFAULT</code></p> <p>No special attributes</p> <p><code>SE_DONTENUM</code></p>

---

---

The member is not enumerated when the `for...in` statement is used on this object.

`SE_DONTDELETE`

Using the `delete` operator on this member is ignored.

`SE_READONLY`

Attempts to write to the member are ignored.

`SE_IMPLICIT_THIS`

Only objects can have this attribute, it has no meaning for a non-object member. When the object is called as a function, the `this` variable is added to the function's scope chain. See the [SCOPING](#) section for more information.

`SE_IMPLICIT_THIS`

Only objects can have this attribute, it has no meaning for a non-object member. When the object is called as a function, the `this` variable's parents are added to the function's scope chain. See the [SCOPING](#) section for more information.

`SE_DYNA_UNDEF`

Only objects can have this attribute, it has no meaning for a non-object member. Dynamic callbacks of the object are only invoked if the object does not have the member being worked on in its internal store. See [DYNAMIC OBJECTS](#) for more information.

SEE: [seSetAttribs](#)

---

## seCompare

SYNTAX: `sebool  
seCompare(secontext se, seobject obj1,  
  semember mem1,  
  seobject obj2,  
  semember mem2,  
  slong *result);`

WHERE: `se` the context the members belong to

`obj1` the object half of the Object,Member pair for the first operand.

`mem1` the member half of the Object,Member pair for the first operand.

`obj2` the object half of the Object,Member pair for the second operand.

`mem2` the member half of the Object,Member pair for the second operand.

`result` an output parameter returning -1, 0, or 1 to indicate that the first member is less than, equal to, or greater than the second member.

---

RETURN:	TRUE if the two members are equal
DESCRIPTION:	This function uses the ECMAScript rules to determine the relationship between the two variables. Since ECMAScript only defines a less-than relationship, this routine internally has to compare twice to give all the possibilities. For that reason, you can narrow the information you are interested in by specifying one of the following special values as the <i>result</i> parameter. In that case, only the boolean return of the function is used as described in each case:  SE_COMP_EQUAL Determine if the two members are equal  SE_COMP_LESS Determine only if the first member is less than the second.
SEE:	None

---

## OBJECT ACCESS ROUTINES

### seObjectMemberCount

---

SYNTAX:	<code>sememcount seObjectMemberCount(secontext se, seobject object);</code>
WHERE:	<i>se</i> the context the object is a part of  <i>object</i> the object to query
RETURN:	The number of members the object has.
DESCRIPTION:	This call returns the number of members an object has. The usual use is to iterate through all the members, using SE_INDEX () from 0 to one less than the result of this call.
SEE:	<a href="#">seObjectMemberName</a> , ObjectMemberCountDirect

---

### seObjectMemberCountDirect

---

SYNTAX:	<code>sememcount seObjectMemberCountDirect(secontext se, seobject object);</code>
WHERE:	<i>se</i> the context the object is a part of  <i>object</i> the object to query
RETURN:	The number of members the object has.
DESCRIPTION:	This call returns the number of members an object has. The usual use is to iterate through all the members, using SE_INDEX () from 0 to one less than the result of this call. This version of the call ignores the object callback <code>getMaxIndex</code> and returns the number of members the object has in its internal storage. It is useful for implementing object callbacks.
SEE:	<a href="#">seObjectMemberName</a> , ObjectMemberCount

---

## seObjectMemberName

---

SYNTAX:	<pre>seconstcharptr seObjectMemberName(secontext se,                    seobject object,                    semember member,                    sememcount *len);</pre>
WHERE:	<p><code>se</code> the context the member is a part of</p> <p><code>object</code> the object the member is in</p> <p><code>member</code> which member to get the name of</p> <p><code>len</code> the length in characters of the member name</p>
RETURN:	The member name.
DESCRIPTION:	<p>This function is used to get the name of a member. It is most useful when enumerating the members of an object using the <code>SE_INDEX()</code> member access macro. If there is no such member then a blank string is returned and <code>SE_RETURN</code>, <code>SE_ERROR</code> will have been set.</p> <p>Unlike <code>seGetName</code>, only the members name is returned, not a fully-qualified variable name.</p> <p>The returned value is treated just like a return from <code>seGetStringEx</code> in terms of its lifetime, following the usual ScriptEase lifetime rules.</p>
SEE:	<code>seGetStringEx</code> , <code>seGetName</code> , <code>seObjectMemberCount</code>

---

## selsFunc

---

SYNTAX:	<pre>sebool seIsFunc(secontext se,seobject object,          semember member,          sebool *script);</pre>
WHERE:	<p><code>se</code> the context the object belongs to</p> <p><code>object</code> the object half of an Object,Member pair.</p> <p><code>member</code> the member half of an Object,Member pair.</p> <p><code>script</code> an output parameter, <code>TRUE</code> if the function is a script function as opposed to a wrapper function.</p>
RETURN:	The boolean <code>TRUE</code> if the object is a function.
DESCRIPTION:	All functions in ScriptEase are objects, but not all objects are functions. The API call lets you determine if an object is in fact a function. If it is, the output boolean <code>script</code> will be <code>TRUE</code> if the function is a script function, <code>FALSE</code> if it is a wrapper function.
SEE:	<code>selsArray</code>

---

## selsArray

---

SYNTAX:	<pre>sebool seIsArray(secontext se,seobject object,           semember member,</pre>
---------	--

---

---

	<code>sememcount *length);</code>
WHERE:	<p><code>se</code> the context the object belongs to</p> <p><code>object</code> the object half of an Object,Member pair.</p> <p><code>member</code> the member half of an Object,Member pair.</p> <p><code>length</code> an output parameter filled in with one more than the highest numbered element, 0 if no numbered element.</p>
RETURN:	The boolean <code>TRUE</code> if the object is an ECMA <code>Array</code> . Note that objects that are not true <code>Arrays</code> can still have numbered elements. Thus, the <code>length</code> parameter will be filled in for all objects, though it will usually be 0.
DESCRIPTION:	Determine if an object is an ECMA <code>Array</code> .
SEE:	<code>seIsFunction</code> , <code>seSetArray</code>

---

## seSetArray

---

SYNTAX:	<p><code>sebool</code></p> <p><code>seSetArray(secontext se,seobject object, sememcount length);</code></p>
WHERE:	<p><code>se</code> the context the object belongs to</p> <p><code>object</code> the object to adjust</p> <p><code>length</code> one more than the new max element</p>
RETURN:	This function returns <code>TRUE</code> if the object was adjusted, <code>FALSE</code> if it was already an <code>Array</code> and no elements were eliminated.
DESCRIPTION:	<p>This call turns an object into an ECMA <code>Array</code> and adjust its elements. Any numbered element greater than or equal to the <code>length</code> is deleted. In addition, the object is permanently marked as an ECMA <code>Array</code> object. This means that its <code>length</code> element corresponds to the numbered elements and adjusting either adjusts the other just as for an <code>Array</code>.</p> <p>If you want to turn an object into an <code>Array</code> without altering any elements, use <code>SE_MAX_INDEX</code> as the <code>length</code> parameters.</p>
SEE:	<code>seIsArray</code>

---

## seShareReadObject

---

SYNTAX:	<p><code>sebool</code></p> <p><code>seShareReadObject(secontext se,seobject object);</code></p>
WHERE:	<p><code>se</code> the context the object belongs to</p> <p><code>object</code> the object to make shared read</p>
RETURN:	This function returns <code>TRUE</code> if the object was successfully shared for reading, <code>FALSE</code> if it could not be.
DESCRIPTION:	Calling this routine makes the given object, and all its children, read-only and shareable. The object handle no longer follows the usual <code>ScriptEase</code> lifetime rules but rather is valid until the

---

---

ScriptEase engine is cleaned up using the `seTerminate` call. All shared objects exist for the life of the program. The `seobject` handle passed to the routine can be used from then on in any context.

When using this routine, you must remember that any object and all its children are shared. This means the object's base class, which it refers to via its `_prototype` is also shared. If you have a complicated object hierarchy, you may end up sharing a large number of objects. All these objects will persist until the program terminates the ScriptEase engine. Also remember that shared objects and their children become read-only to all contexts, including the one that originally shared them.

Objects can only be made sharable when there is a single context existing. You must mark all objects you wish to share before making additional contexts. This routine will fail once two or more contexts exist.

## VARIABLE WRITING

**sePutBoolEx**

**sePutNumberEx**

**sePutPointerEx**

**sePutObjectEx**

**sePutStringEx**

**sePutUndefinedEx**

**sePutNullEx**

---

```
SYNTAX:      sebool
              sePutBoolEx(secontext se,seobject obj,
                          semember mem,
                          int fl,
                          sebool val);

              sebool
              sePutNumberEx(secontext se,seobject obj,
                            semember mem,
                            int fl,
                            senumber val);

              sebool
              sePutPointerEx(secontext se,seobject obj,
                             semember mem,
                             int fl,
                             void *val);

              sebool
              sePutObjectEx(secontext se,seobject obj,
```

---

---

```
    semember mem,  
    int fl,  
    seobject val);
```

```
    sebool  
sePutStringEx(secontext se,seobject obj,  
              semember mem,  
              int fl,  
              seconstcharptr val,  
              sememcount len);
```

```
    sebool  
sePutUndefinedEx(secontext se,seobject obj,  
                 semember mem,  
                 int fl);
```

```
    sebool  
sePutNullEx(secontext se,seobject obj,  
            semember mem,  
            int fl);
```

WHERE:

`se` the context to put the variable to

`object` the object half of an Object,Member pair

`member` the member half of an Object,Member pair

`fl` flags determining how the variable is stored

`val` the value to put, type based on which routine you are using

`len` for strings, the length of the item in characters for strings, or `SE_PS_STRLEN` to let `sePutStringEx` use `strlen_sechar` to determine the length of the string.

RETURN:

The boolean `TRUE` if the member was created, `FALSE` if it already existed.

DESCRIPTION:

These functions are the inverse of the `seGetXXX` versions, they put a value into the given Object,Member location. Like their get counterparts, these functions have versions that make the flags implicit in their name. However, there is one additional flag, `SE_GF_MUST`. `SE_GF_MUST` means that the value should ignore the `SE_READONLY` attribute. This eases updating internal members in your objects that should be read-only for the script but not for you. It is equivalent to turning off the read-only bit, putting the value, then turning it back on. It is most-often used in combination with `SE_GF_DIRECT`. Here are the name/flag equivalents using `sePutNumberEx` as an example:

```
sePutNumber(...) =  
sePutNumberEx(...,SE_GF_DEFAULT)
```

```
sePutDirectNumber(...) =  
sePutNumberEx(...,SE_GF_DIRECT)
```

```
seMustPutNumber(...) =  
sePutNumberEx(...,SE_GF_MUST)
```

```
seMustPutDirectNumber(...) =  
sePutNumberEx(...,SE_GF_MUST|SE_GF_DIRECT)
```

---

---

The `sePutStringEx` call has two extra possible flags, `SE_PS_USEPOINTER` and `SE_PS_BORROWPOINTER`. Normally, any string passed to the core is copied and retained internally. With these flag, a particular string pointer is given to the core. For `SE_PS_USEPOINTER`, the memory pointed to must have previously been allocated using one of the ScriptEase allocation routines. ScriptEase will free this pointer when it finishes using it, so you are giving up control of it permanently. For `SE_PS_BORROWPOINTER`, the ScriptEase core will use the pointer but never free it. This second flag is intended to use in conjunction with constant strings or strings that last the life of your application.

In either case, the string must be `'\0'`-terminated. This means there must be an extra `'\0'` at the end of the string beyond the number of characters specified in the length. This character is not considered to be part of the string and should not be included in the length tally.

SEE: None

---

## seDelete

---

**SYNTAX:** `sebool  
seDelete(secontext se, seobject obj,  
          semember mem);`

**WHERE:** `se` the context to remove the member from  
`obj` the object half of the Object,Member pair  
`mem` the member half of the Object,Member pair

**RETURN:** The boolean `TRUE` if the member was deleted or did not exist, `FALSE` if it could not be deleted such as trying to delete a virtual object's member.

**DESCRIPTION:** This call deletes a member of an object. `seDelete` is not affected by the `SE_DONTDELETE` flag (only the `delete` operator is affected.) If you would like to respect the flag, use `seGetAttribs` to check attributes before deleting a member.

**SEE:** [seGetAttribs](#)

---

## seMakeObject

---

**SYNTAX:** `seobject  
seMakeObject(secontext se);`

**WHERE:** `se` the context to create the object in

**RETURN:** A handle to the created object.

**DESCRIPTION:** This call creates a new object. The returned object handle follows the standard object lifetime rules described in the [Lifetimes](#) chapter. The returned object is blank, meaning it has no members. You'll usually want to store the object using

---

---

`sePutObject`, either to assign it to a variable or return it as the result of your wrapper function.

SEE: [seMakeStack](#), [sePutObject](#)

---

## seMakeStack

---

SYNTAX: `seobject`

```
seMakeStack(secontext se);
```

WHERE: `se` the context to create the object in

RETURN: A handle to the created object (stack).

DESCRIPTION: This call creates a new stack. The returned object handle follows the standard object lifetime rules described in [Lifetimes](#).

A stack is an object and can be used wherever an object can be used. However, you should not use stacks as just another type of object, as stacks are significantly slower to manipulate than objects. Stacks do have the benefit of guaranteeing that members will remain in the order they are created, so that `SE_INDEX(0)` is always the first member created, `SE_INDEX(1)` is the second, and so forth. Regular objects do not have this property. Stacks are used when needing to pass a list of items to the API, such as the parameters or the scope chain to `seEval`.

SEE: [seMakeObject](#), [seEval](#)

---

## sePutWrapper

---

SYNTAX: `sebool`

```
sePutWrapper(secontext se,
             seobject obj,
             semember mem,
             seconstcharptr name,
             seWrapper wrapper_func,
             int minArgs,
             int maxArgs,
             uword32 funcFlags,
             uword32 varFlags,
             void *data);
```

WHERE: `se` the context to put the wrapper to

`obj` the object half of the Object,Member pair

`mem` the member half of the Object,Member pair

`name` the name of the function for error reporting

`wrapper_func` the function

`minArgs` the minimum arguments to the function

`maxArgs` the maximum arguments to the function

`funcFlags` the function flags

`varFlags` the variable-type flags

`data` data associated with the function.

---

---

RETURN:	A boolean, TRUE if the put was successful.
DESCRIPTION:	This call turns a variable into a wrapper function. See the " <a href="#">Wrapper functions</a> " chapter for complete details about wrapper functions. The parameters to this function correspond to the parameters to the <code>SE_FUNCTION()</code> library table entry. Since you specify the exact Object,Member location to put the new wrapper function in, the <code>name</code> parameter does not indicate where to put the function. It is used if an error message occurs related to the function.
SEE:	None

---

## seSetCallbacks

---

SYNTAX:	<pre> sebool seSetCallbacks(secontext se,                 seobject obj,                 semember mem,                 const struct seObjectCallbacks *cbs); </pre>
WHERE:	<p><code>se</code> the context the object is a part of</p> <p><code>obj</code> the object half of the Object,Member pair</p> <p><code>mem</code> the member half of the Object,Member pair</p> <p><code>cbs</code> a pointer to the callbacks structure</p>
RETURN:	True. This will only return non-TRUE if compiling with <code>JSE_MIN_OBJ_SIZE</code> and if there is a non-recoverable memory allocation error.
DESCRIPTION:	This routine sets the object callbacks for an object. If the variable is not an object, nothing is done. Otherwise, the internal table of object callbacks for the object is changed to point to the given table. See <a href="#">DYNAMIC OBJECTS</a> for a complete discussion of dynamic objects and object callbacks.
SEE:	<a href="#">seEnableDynamicMethod</a>

---

## seEnableDynamicMethod

---

SYNTAX:	<pre> restoreDynamicMethodState seEnableDynamicMethod(     secontext se,     seobject obj,     semember mem,     enum whichDynamicCallback whichCallback,     sebool enable,     restoreDynamicMethodState restore_state); </pre>
WHERE:	<p><code>se</code> the context the object is a part of</p> <p><code>obj</code> the object half of the Object,Member pair</p> <p><code>mem</code> the member half of the Object,Member pair</p> <p><code>whichCallback</code> which method to enable/disable, this may be any of:</p> <p style="text-align: center;"><code>SE_GET_CALLBACK</code></p>

---

---

```
SE_PUT_CALLBACK
SE_HASPROP_CALLBACK
SE_CANPUT_CALLBACK
SE_DELETEPROP_CALLBACK
SE_DEFAULTVALUE_CALLBACK
SE_OPERATOROVERLOAD_CALLBACK
SE_GETBYINDEX_CALLBACK
SE_GETNAMEBYINDEX_CALLBACK
SE_GETMAXINDEX_CALLBACK
SE_ALL_CALLBACK /* all of the above */
```

enable whether to enable dynamic method

restore\_state NULL for first call in pair, for second call set to value returned by the first call

RETURN: In first call in pair, this returns the value to be passed as restore\_state for second call. For second call in pair the return value has no meaning.

DESCRIPTION: Enable (if enable is TRUE) the calling of the dynamic method named methodName else disable calling of that dynamic method. These methods are disabled during a callback of that method (i.e. put is disabled while within put to prevent recursion). This is a risky function and not a default part of the API. To enable this API function compile with JSE\_ENABLE\_DYNAMETH.

This function is always used in a pair. For the first call in the pair restore\_state should be NULL. For the second call, which will undo the first, restore\_state must be the value returned by the first call of the pair.

SEE: [seSetCallbacks](#)

---

## seConvert

---

SYNTAX:           void  
          seConvert(secontext se,  
                    seobject obj,  
                    semember mem,  
                    seConversionTarget type);

WHERE: se the context containing the variable  
       obj the object half of an Object,Member pair  
       mem the member half of an Object,Member pair  
       type the type to convert to.

RETURN: None

DESCRIPTION: This routine retrieves the value using a get from the Object,Member pair, converts it, and puts it back to the same location. The possible conversions are:

```
SE_TOPRIMITIVE
```

Convert to a primitive value. A primitive value is a non-object

---

---

value.

SE\_TOBOOLEAN

Converts to a boolean

SE\_TONUMBER

Converts to a number

SE\_TOINTEGER

Converts to an integer. It is system-dependent the range of an integer, but it corresponds to the `int` type on the system.

SE\_TOINT32

Converts to a signed 32-bit integer

SE\_TOUINT32

Converts to an unsigned 32-bit integer

SE\_TOUINT16

Converts to an unsigned 16-bit integer

SE\_TOSTRING

Converts to a string

SE\_TOOBJECT

Converts to an object.

SEE: None

---

## seSetAttribs

---

SYNTAX:           void  
                  seSetAttribs(secontext se,  
                                  seobject obj,  
                                  semember mem,  
                                  seAttributes attributes);

WHERE:            se the context containing the variable  
  
                  obj the object half of an Object,Member pair  
  
                  mem the member half of an Object,Member pair  
  
                  attributes the attributes to assign to the variable

RETURN:           None

DESCRIPTION:     This call sets the variable's attributes. The attributes can be any of the following, |'d together:

SE\_DEFAULT

The default, no special attributes

SE\_READONLY

Any attempt to update the member is ignored

SE\_DONTDELETE

Attempts to delete the member using the ECMAScript `delete`

---

---

operator are ignored

SE\_DONTENUM

The member is not included in `for...in` enumerations

The following flags apply only if the variable is an object:

SE\_DYNA\_UNDEF

Dynamic callbacks for the objects are only used if the object does not contain the member in the ScriptEase internal storage for the object.

SE\_IMPLICIT\_THIS

When the function is executed, the `this` variable is added to the front of the scope chain so all members of `this` are visible without putting `this.` in front of them. This is exactly as if the entire body of the function was wrapped in the statement `with( this ) ...`. This behavior is similar to how C++ member functions work.

SE\_IMPLICIT\_PARENTS

Similar to SE\_IMPLICIT\_THIS, the parents of the `this` variable are put into the scope chain. This chain begins with `this.__parent__` and continues as long as each such object itself has a `__parent__` property. Note that there are two underscores on each side of `parent` above. This is useful for browsers in which event handlers can refer to variables in the enclosing element, document, and window. By chaining these objects together using `__parent__` and adding SE\_IMPLICIT\_THIS and SE\_IMPLICIT\_PARENTS to the event handler function, the desired behavior is achieved.

## seAssignEx

---

SYNTAX:            sebool  
                   seAssignEx(secontext se, seobject destObj,  
  semember destMem,  
  seobject srcObj,  
  semember srcMem,  
  int flags);

WHERE:            se the context the members are a part of  
  
                   destObj the desination object half of the Object,Member pair  
  
                   destMem the desination member half of the Object,Member pair  
  
                   srcObj the source object half of the Object,Member pair  
  
                   srcMem the desination member half of the Object,Member pair  
  
                   flags the assignment flags

RETURN:           A boolean, TRUE if the destination member was created, FALSE

---

---

if it already existed.

DESCRIPTION: This function does a get on the source Object,Member followed by a put of that value to the destination Object,Member.

seAssign is similar to the sePut functions in that it has the Must and Direct name forms as an alternative to the flags.

SEE:

---

## seThrow

---

SYNTAX: `void  
seThrow(secontext se,seconstcharptr message,  
...);`

WHERE: se the current context

message the message of the error message in standard ScriptEase format.

... printf-style arguments

RETURN: None

DESCRIPTION: An error object is constructed and set up in the SE\_RETURN object. In addition, the error flag is turned on. If the wrapper function calling seThrow returns after this call, it's result will be the given error.

The standard error message format for ScriptEase allows information on the type of the error to be included. By default, a stock Exception object is constructed with the text passed to this function. The extended form of the string is:

```
!TYPE NUM: MESSAGE
```

For instance, you could pass:

```
!SyntaxError 9999: You made a mistake.
```

The TYPE indicates the type of the error. An error object of this type is constructed to contain the error. The error types are:

SyntaxError

ReferenceError

ConversionError

ArrayLengthError

TypeError

URIError

EvalError

RegExpError

These types are defined by ECMA, including what errors are generated in normal error situations. When writing your own wrapper functions, pick the error type you feel is most

---

---

appropriate.

The `NUM` indicates a resource number for your error message. Values of 10000 or more are reserved for user errors, and you should use one. These numbers are used by the `seGetResourceFunc` to internationalize the text associated with various text strings, including error messages.

`MESSAGE` is the text of the error message.

When the internal exception object is generated (for `seThrow` exceptions or any internally generated exception), these properties of that object are created:

- `name` - Name of the exception class, e.g. "SyntaxError"
- `message` - text of error, e.g. "9999: You made a mistake."
- `fileName` - Name of the source file where error occurred, if available, e.g. "c:\foo\myscript.jsa"
- `lineNum` - Line number if file where error occurred, if available, e.g. "173"
- `functionName` - Name of executing function where error occurred, if available, e.g. "foobar"

## EXECUTING SCRIPTS

### seEval

---

SYNTAX:            `sebool`  
`seEval(secontext se,`  
                  `void *to_interpret,`  
                  `int interp_type,`  
                  `seconstcharptr text_args,`  
                  `seobject stack_args,`  
                  `uword32 flags,`  
                  `struct seEvalParams *params);`

WHERE:            `se` the context to execute in  
  
                  `to_interpret` the script or function to execute  
  
                  `interp_type` what the `to_interpret` parameter is  
  
                  `text_args` arguments as a text string  
  
                  `stack_args` arguments on a stack `seobject`  
  
                  `flags` options on how to eval  
  
                  `params` eval params

RETURN:            A boolean, `TRUE` if the evaluation was successful

DESCRIPTION:     See “Using `seEval`” in the chapter “Script Execution Topics” for details on using the `seEval` ScriptEase API call.

SEE:                `seExec`, `seEnd`

---

## seExec

---

**SYNTAX:**            sebool  
                  seExec(secontext se);

**WHERE:**             se the context to execute the next statement on

**RETURN:**            TRUE if there are more statements to execute, FALSE when the seEval is completed.

**DESCRIPTION:**      This routine executes one script statement from a script started with seEval using the SE\_START option. When the eval is completed, the return value will be stored in the SE\_RETURN object.

**SEE:**                seEval, seEnd

---

## seEnd

---

**SYNTAX:**            void  
                  seEnd(secontext se);

**WHERE:**             se the context running the script to be aborted.

**RETURN:**            None

**DESCRIPTION:**      This call aborts a script started with seEval using the SE\_START option. This will immediately terminate the script which is being executed one statement at a time. There is no return value from an aborted script.

**SEE:**                seEval, seExec

---

## sePrecompile

---

**SYNTAX:**            ubyte \*  
                  sePrecompile(secontext se,  
                                const void \*to\_interpret,  
                                int interp\_type,  
                                sememcount \*len,  
                                struct seEvalParams \*params);

**WHERE:**             se the context to precompile in

                  to\_interpret the text of the script or the filename to compile

                  interp\_type how to interpret to\_interpret, either SE\_TEXT or SE\_FILE

                  len an output parameter, the length of the returned bytecodes in bytes.

                  params used to get the virtual file and line number only.

**RETURN:**            The bytecodes

**DESCRIPTION:**      This routine compiles a script into the corresponding bytecodes. The file to precompile is specified exactly like seEval and must be either SE\_TEXT or SE\_FILE. The given file is precompiled and the resulting bytecodes are returned. In addition, len is filled in with the size of the resulting bytecodes. Usually, these bytecodes are then written to disk for use later. The bytecodes

---

---

should be treated as an array of `*len` bytes.

The bytecodes can be passed as the item to evaluate in a later `seEval` call with `SE_PRECOMP` as the type. The bytecodes must be freed using `seFreeBytecodes`. Although the script is precompiled, it is not added to the context or run. The context will be unchanged as a result of this call.

You can provide the optional `params` structure. Only the virtual filename and `linenumber` members of the structure are used.

SEE: [seFreeBytecodes](#)

---

## seFreeBytecodes

---

SYNTAX: `void  
seFreeBytecodes(secontext se,ubyte *codes,  
sememcount len_unused);`

WHERE: `se` any valid context

`codes` the bytecodes returned from `sePrecompile`

`len_unused` the number of bytes, this parameter is not used

RETURN: None

DESCRIPTION: Call this routine to free the bytecodes given to you from [sePrecompile](#) after you are finished using them, such as after writing them to disk.

SEE: [sePrecompile](#)

---

## selsBreakpoint

---

SYNTAX: `sebool  
seIsBreakpoint(secontext se,  
seconstcharptr filename,  
uint lineNumber);`

WHERE: `se` the context to check in

`filename` the file interested in

`lineNumber` the line in that file

RETURN: A boolean, `TRUE` if the line is a valid breakpoint.

DESCRIPTION: This function is provided for use by a debugger. It checks to see if it is possible for any function currently loaded to break at the given file and line. This check is intended to be called in response to a user request to set a breakpoint. Be warned that this call is very slow. The filename must match one of the currently loaded filenames (which can be found in the `SE_FILENAMES` object) or it cannot be a breakpoint and this function will return `FALSE`. If you have a `seFindFileFunc` callback in your context (described in [The seContextParams Structure](#)), the filenames that are used are the ones returned from this function, the translated filename, not the untranslated ones passed to the callback.

# The Debugger

Many customers desire to add debugger-like operations to their ScriptEase application. Some want their own debugger instead of the Nombas-provided one while others have similar needs that a debugger doesn't exactly fill such as writing out a trace log. Later in this chapter, we will examine hooking the Nombas debugger into your application. The first part of this chapter will involve writing a simple text-based debugger to see how you can go about it.

---

## SECONTINUEFUNC

The proper place to put a debugger hook is in the `seContinueFunc` specified in your ScriptEase `seContextParams` structure. This function is called after each statement is processed. An alternative would be to evaluate a script using `seEval` with the `SE_START` option and do debugging work after each call to `seExec`. The problem with this alternative is that calls to wrapper functions are atomic. Therefore, if a wrapper function itself invokes code, such as a script call to `eval()`, your debugging work would not be called during that code.

The debugger must regain control after each statement to be useful. The easiest way to force this is to use `seGetContextParams` and set the `SE_OPT_DEBUGGER` flag on, like this:

```
struct seContextParams *params = seGetContextParams(se);
params->seOptions |= SE_OPT_DEBUGGER;
```

---

## THE SIMPLE DEBUGGER

For this simple debugger, it is assumed that the application will be a console-based application so standard C functions such as `printf` are available. The output from the script and the debugger will be intermixed on this console. That suffices for a simple debugger. The implementation of this debugger will help you to understand how to write debuggers and debugger-like programs to add to your application in a simple way. The ScriptEase debugger is a much more complex example of a full debugger.

This debugger is able to debug multiple scripts, such as a multi-fiber application (described in "[Fibers and Threads](#)") simultaneously because it store all information for each context in that context.

The simple debugger function follows. To use it in your application, simply define an `seContinueFunc` callback in your application and call this function. A ScriptEase ISDK sample application using this debugger can be found as the `debug sample`.

```
#define DBG_NEXT    SE_MEM("debugger_next_depth")
#define DBG_OFF     SE_MEM("debugger_off")
#define BREAK_LIST SE_MEM("debugger breakpoints")

/* A place to save commands between calls */
```

```

static sechar commandbuf2[256];

    sebool
simple_text_debugger(secontext se)
{
    sechar linebuf[256];
    sechar commandbuf[256];
    sebool is_break = FALSE;
    seobject list;
    int frame = 0; /* current stack frame */

    /* Make sure our breakpoint list object exists and is an
     * object
     */
    if( seGetType(se,SE_SERVICES,BREAK_LIST)!=SE_TYPE_OBJECT )
    {
        sePutObject(se,SE_SERVICES,BREAK_LIST,seMakeObject(se));
    }

    list = seGetObject(se,SE_SERVICES,BREAK_LIST);

    sprintf_sechar(linebuf,"%s:%g",
        seGetString(se,SE_STACK_INFO(0),SE_SI_FILENAME,NULL),
        seGetNumber(se,SE_STACK_INFO(0),SE_SI_LINENUM));
    if( seExists(se,list,SE_UNIMEM(linebuf)) )
        is_break = TRUE;

    /* When executing a print statement, breakpoints should
     * not be called, I think. I can see it both ways, but this
     * way makes more sense to me.
     */
    if(seExists(se,SE_SERVICES,DBG_OFF) )
        return TRUE;

    if( is_break && seExists(se,SE_SERVICES,DBG_NEXT) )
        printf_sechar("\nBreakpoint reached.\n\n");

```

---

## INTEGRATING THE SCRIPTEASE DEBUGGER

The ScriptEase debugger can be used to debug scripts being run in your ScriptEase:ISDK application. This section explains the steps you need to take to enable debugger support in your application.

There are two basic ways a debugging session can operate. First, your application may wish to connect to the debugger and debug a script. For instance, you may have a menu option to debug a script. In this case, your application runs normally until the time you wish to debug a particular script. When that debugging is complete, your application continues as normal. The second way to initiate debugging is by the command of the debugger. Typically, the ScriptEase IDE is being used to edit a script meant to be run by your application. When the user

wants to try the script out, your application is invoked in the background to execute the script. Your application recognizes this situation by the presence of a `/debug` command-line switch. The rest of the command-line consists of the script to be run and any parameters to be passed to the script.

In either case, ScriptEase API calls are provided to establish a connection with the debugger and execute the script under the debugger's control. The connection between an application and the ScriptEase debugger is a TCP-IP socket. Connections can be established remotely, when the application and debugger reside on different machines.

## THE CONTINUE FUNCTION

The first step in integrating debugging support into your application is modifying the continue functions. Your application may or may not have such a function currently. If it does not, you will need to add one in order to integrate with the debugger. The continue function is specified by one of the context parameters passed when creating a new context. At the end of your continue function, you need to invoke this ScriptEase debugger API call:

```
void
seDbgContinue(secontext se);
```

This call communicates with debugger. This is a blocking call so it will not return until the debugger gives the application more work to perform. A second, non-blocking version of this API is available:

```
sebool
seDbgNBContinue(secontext se, sememcount timeout);
```

This version will return to you after the given number of milliseconds as specified by the timeout. If the function returns `FALSE`, you may exit from the continue function. However, if it returns `TRUE` you must call the routine again before exiting from the continue function. The continue function itself consists of any code that must be executed periodically. You would use this call as in this example:

```
SE_CALLBACK( void )
myContinueFunc(secontext se)
{
    do
    {
        /* your existing continue code here */
    }
    while( seDbgNBContinue(se, TIMEOUT) );
}
```

The timeout you specify depends on the needs of your code. For an application that handles GUI interface interaction in its continue function, responsiveness is important. A timeout of 100 milliseconds would be a reasonable choice in this case.

Once you have modified or created your continue function, it must be called after each statement in the script is executed. This may not be the case depending on the parameters passed to your `seEval` calls or to such calls in libraries you are using. To ensure this is always the case, set the `SE_OPT_DEBUGGER` flag in the context parameter's options. There is no need to alter any of your `seEval` calls.

## THE AT ERROR FUNCTION

This step is very similar to the continue function, you must make a call to a ScriptEase debug API in your at-error function. If you do not currently have one, you must add one. It is in the context parameter structure just like the continue function is.

```
void
seDbgAtError(secontext se);
```

This function will not lock your application up because it uses your continue function internally while it is waiting.

## INVOKING THE DEBUGGER

To connect to the debugger, the application needs to know the host machine name and the port the debugger is running on. This information can be obtained in a number of ways such as by preferences settings for the application user. However, when an application is started by the debugger, it is always given a command-line switch to tell it this information. The switch is of the form:

```
/debug=<host>:<port>
```

The application should extract and use the provided host and port if this switch is passed to it. In addition, it should immediately connect to the debugger and execute the script passed on its command-line, as previously described. If there is no such switch, the application can debug at any time by connecting to an arbitrary debugger on any machine. The usual port for a ScriptEase debugger is `SEDBG_STANDARD_PORT`.

In any case, once the application has the host and port, it connects to the debugger using the following ScriptEase debug API call. The `password` is optional, needed if you want the debugger's user to provide this password before debugging your application. Use `NULL` if you don't want a password. The `application_id` is arbitrary text to identify your application.

```
sebool
seDbgConnect(secontext se,
             seconstcharptr host,
             uint port,
             seconstcharptr application_id,
             seconstcharptr password);
```

The result is a boolean indicating success. If it is `FALSE`, then the debugging connection could not be established. To determine the reason for the failure, use this ScriptEase Debug API call:

```
seconstcharptr
seDbgLastError(secontext se);
```

If a connection cannot be established, a text explanation of the failure can be retrieved using this call.

Once the debug session is begun, it must be terminated with this call:

```
void
seDbgStop(secontext se);
```

Normally this call is used when the script finishes executing. However, it can be used while the script is executing to terminate debugging of the script. The script will continue as normal as this call only stops the debugger control of the application.

Between connecting and stopping, you execute a script using `seEval`. It is possible to leave the connection open and run multiple scripts. The debugger will handle them all. However, doing so may confuse the debugger user. It is usually better to use `seDbgStop` after the script is done and reconnect to the debugger if another script needs to be debugged.

## INVOKING THE DEBUGGER ON AN ERROR

It is often desirable to invoke the debugger only if an error occurs in the script so that the user can debug it. You can do this by initializing the debugger connection not when the script starts but rather only when the error occurs. This is done in the `seAtErrorFunc` callback in the context parameters. You don't do this in the `sePrintErrorFunc` found in the same parameters structure. The first callback is called when the error occurs. The script is still executing at the point of the error with the correct variables and call stack for the error. The second function isn't called until the script terminates with the error, by which time the context of the error is lost.

In addition, the other steps of the debugger integration mentioned above must still be completed. The only difference is that you do not call `seDbgConnect` before executing any scripts but rather only in response to an error. Here is an example `seAtErrorFunc` taken from ScriptEase Desktop Win32 which demonstrates invoking the debugger at the point of the error:

```
/* This at-error function will, if debugger support is enabled,
 * give the user the option to connect to the debugger to
 * debug the script from the point of the error.
 */
static SE_CALLBACK( void )
SeAtErrorFunc(secontext se,struct seAtErrorInfo *info)
{
#if SE_DEBUGGER_SUPPORT==1 && defined(__JSE_WIN32__)

/* If this is an untrapped error, debug it at the point
 * of error. Untrapped errors are the ones that will
 * eventually be printed to the screen. We don't
 * debug trapped errors because those are usually
 * used for program flow control with throw/catch.
 */
if( !seDbgConnected(se) &&
    !info->trapped &&
    MessageBox(0,seGetString(se,SE_RETURN,SE_VALUE,NULL),
               "Would you like to debug this error?",
               MB_YESNO)==IDYES
    )
{
    struct seContextParams *params;

    params = seGetContextParams(se);
    params->seOptions |= SE_OPT_DEBUGGER;

    if( !seDbgConnect(se,"localhost",SEDBG_STANDARD_PORT,
                      "Scriptease Desktop Win32",NULL) )
    {
```

```

sememcount i;

system("start workshop.exe");

/* Wait 10 seconds checking every 1/10th if
 * debugger is ready
 */
for( i=0;i<100;i++ )
{
    Sleep(100);
    if( seDbgConnect(se,"localhost",SEDBG_STANDARD_PORT,
                    "Scriptease Desktop Win32",NULL) )
        break;
}
}

seDbgAtError(se);
#endif
}

```

---

## THE SCRIPTEASE DEBUGGER PROTOCOL VERSION 1.0

It is possible to replace the ScriptEase debugger with a custom debugger. This section describes the protocol that the debugger is expected to understand.

Debugging occurs on TCP-IP sockets. The debugger must provide a port to receive debug requests on. If the debugger starts up an application to execute a script, it will give the host and port it is monitoring to the application via the command-line switch `/debug=HOST:PORT`. Applications can also run their scripts under a debugger at any time if they know a host and port combination a debugger is currently monitoring. This is especially useful to debug applications remotely. The ScriptEase debugger uses the port `0xdead` so that all applications can find it. Custom debuggers can use whatever port they like or can mimic the standard debugger's port.

Each socket connection will be an application wishing to debug a script. It is up to the debugger writer if the debugger will allow multiple debug sessions simultaneously. If it does not, it should still accept the connection and use the DENIED response, described below, to refuse the debugging indicating that a debug session is currently processing.

Once a connection is established, the protocol consists of text messages sent back and forth between the debugger and the application as described below. The description of these messages specify the text in uppercase. This is done for clarity, as the commands are case-insensitive. However, on some systems filenames are case-sensitive so the debugger must preserve the case on all filenames. In the following description, parameters to the command are written in lowercase. The lowercase text is meant to describe the purpose of the parameter. The parameter is to be replaced by the appropriate value.

All text send by the application and the debugger to each other using this protocol is in ascii except for the specific exceptions mentioned below. All command lines are in ascii. Unicode can appear in only a specific few places. Two of the commands can optionally return unicode strings. When they do, they

have a different response to indicate their return is unicode. The last place unicode can appear is in filenames. The filenames will be ascii strings, but unicode characters can be indicated by escaping them. In this case, the sequence `\uXXXX` is used where `XXXX` are exactly four hex characters indicating the value of the unicode character.

All command lines in this protocol are terminated by a `\r\n\r\n` marker. Data lines are always exactly what the data is, so they may have some combination of `\r` and `\n` in them. Data is always identified to be of a certain length by a preceding header line before it is sent. That length is always exactly the number of bytes the data encompasses.

## INITIALIZATION

When the debugger accepts a connection, the first task is to initialize the debug session. Both sides communicate their application name and which ScriptEase debug version they expect. If the application is password-protected, the debugger provides the password. Either side, the debugger or the application, has opportunities to terminate the connection for a number of reasons.

The application begins by identifying itself:

```
SCRIPTEASE DEBUG version application-identifier
```

For instance:

```
SCRIPTEASE DEBUG 1.0 Sewse
```

The version cannot have spaces in it. Whatever text is provided is split by the first whitespace character into the version and the application identifier. Also note that TCP-IP provides the IP address of the connecting application. The application already knows the IP address of the debugger else it would not have been able to establish the connection in the first place. IP addresses are important as they allow both sides to know if a remote debugging session is taking place. The debugger should generally allow all local debugging sessions to take place but will probably want to query its user if a remote debugging session should be allowed.

In the case of a local debugging session, filenames sent by the application will be the same filenames the debugger should display. However, for remote applications the filenames will not match. In a remote debugging session, it is erroneous to display files of the given names even if they exist with the given name on the local machine: the contents of those files may be different on the remote machine. For each new filename, the debugger should use the `SEND FILE` command (described below) to get the contents of the file and make a local copy of that file. The local copy will be stored in a temporary location to be deleted when the session is complete. The debugger will translate filename references to the local copies. In the case of local files that the debugger cannot locate, the same mechanism should still be applied.

The debugger's response to the application is a line of the same format as the application's, with the debugger's identifier string in place of the application's. The version must match exactly, to verify the debugger understands the version. However, if the debugger does not accept the debug session, it instead denies the debug session with the following command:

DENIED text message indicating reason for denial

Some examples include:

```
DENIED Too many active debug sessions currently.
DENIED Version 1.0 is not understood.
DENIED 200.0.1.6 is a known hacker site.
DENIED This debugger is JoeBob's Super App-specific.
DENIED User denied this request.
```

The application has three possible responses to an accepted connection by the server. It can deny the connection itself in the same way the server can. It can accept the connection by:

```
DEBUG BEGUN
```

In this case, the debug connection goes into the main debug mode described below. Finally, the application can ask the server for a password:

```
SEND PASSWORD
```

The debugger responds with:

```
PASSWORD password
```

The application can respond with another `PASSWORD` message if the password was incorrect. If the password is missed three times, the application will give a `DENIED`. Once the password is accepted, the application uses `DEBUG BEGUN` to enter the main debug mode.

## MAIN DEBUG MODE

This is the main loop of the debugging session. It continues until the session is ended by either side closing their socket or by the debugger sending the `QUIT` command. The debugger is always in control, sending a single command at a time for the application to execute. The application always gives a response to each command. If the command is not understood, it results in a `DENIED` response.

Note that it is possible to not use the `GO` command described below and the various breakpoint commands that go along with it. This could be done by using `STEP` only and making the checks yourself in the debugger. This is strongly discouraged. Experimentation has shown that the speed penalty is enormous.

## REPORT

This is the main debugger status command. The application responds with one of these two:

```
LOCATION filename:line-number DEPTH depth
DEPTH 0
```

Note that depth 0 represents being outside of a script. In the first instance, depth will never be 0. When the script reaches its end, the depth will be 0. If the debugger find the depth to be 0 on the first call, it means the script had a syntax error in it. See `GET/STRING` below to retrieve error messages.

Often, the debugger will follow up this command with a `SEND FILE` command if the given filename is one it has not seen before. The `REPORT` command is typically issued when the connection first begins then right after any of the

GO/STEP commands listed below. However, the debugger may use this command more frequently in development to ensure it is properly keeping itself in sync. It can issue this command and check against its internal records and, if they don't match, the debugger has a problem.

If the filename contains spaces, it must be enclosed in quotes (i.e. "filename").

### **SEND FILE filename**

The debugger uses this when remote debugging and finding a new filename. The application responds by sending the file using this format:

```
FILE filename LENGTH length-in-bytes
file contents
FILE DONE

UNICODE FILE filename LENGTH length-in-bytes
file contents
FILE DONE
```

The length field is confirmed by finding FILE DONE at the right place. For files of unicode characters, the length in bytes will be twice the number of unicode characters. Unicode chars are passed in little endian byte order.

It is alternately possible to see a DENIED response from the application. Only filenames sent in a REPORT are valid. This is a check against someone trying to read arbitrary files. If the DENIED message text consists of a single ?, the application is indicating it does not have access to the source text. This is possible when the application is executing compiled scripts. In this case, the debugger will have to make a decision as to what it does in this case. One possibility is to expect the user to run the debugger from the machine that originally compiled those scripts. In this case, the filenames will correspond to files on the debugging machine.

### **CLEAR BREAKPOINTS**

All breakpoints the application has received from the debugger are deleted. This included both kinds of breakpoints, file and line based as well as expression based. Application will respond with:

```
BREAKPOINTS CLEARED
```

### **BREAKPOINT ADD/REMOVE filename:line-number**

Will add or remove a breakpoint at a certain file and line. The application will respond with one of:

```
BREAKPOINT filename:line-number ADDED
BREAKPOINT filename:line-number REMOVED
BREAKPOINT filename:line-number EXISTS
BREAKPOINT filename:line-number NOT FOUND
```

The last two messages are errors in trying to add a breakpoint that already exists or remove one that doesn't.

### **EXPR ADD expression**

An expression is added as a breakpoint. The application responds:

```
EXPR #number ADDED
```

Where the number is the expression number, assigned by the application. Expressions are evaluated after each statement and a break occurs when the expression becomes true.

A warning is in order, because these are full evaluated expressions done after every statement, their presence will drastically slow down execution of the script.

### **EXPR REMOVE #number**

Remove an expression breakpoint using the number returned when it was created. The application responds:

```
EXPR #number REMOVED
EXPR #number NOT FOUND
```

### **GO number**

Tells the application to start executing until it reaches one of the breakpoints, an error, or the depth equals the *number* given above. The application responds:

```
GO COMPLETE
GO COMPLETE WITH ERROR
GO COMPLETE WITH TRAPPED ERROR
GO STOPPED
```

depending on if the go stopped due to an error being received or because of reaching a breakpoint. In the case of an error, an untrapped error indicates that the error message is going to be printed to the user and so should be printed to the debugger's user as well. See `GET` below on how to get the error's value.

Use the depth to implement step over and step out. A normal go should have depth as 0, meaning it only stops when it reaches depth 0 (i.e. the script ends). Use the current depth, retrieved by `REPORT`, to step over. Use the current depth minus one to step out.

Stopping with `TRAPPED ERROR` means that the exception is going to be handled, perhaps by a `try/catch` block. However, often debuggers will have the option to break on any error. If the debugger is not using this option, it will want to ignore trapped error returns. Use `REPORT` to find the current depth and see if the action (step out/step over) is complete. If it is not complete, or in the case of a generic run, just call `GO` again. This same mechanism can be used to trap some errors, such as range errors, but not others. Most debuggers have all kinds of options on exactly which errors should stop execution and which should not.

The final possible response, `GO STOPPED`, happens if the debugger stops the `go` command prematurely. It does this by sending a `STOP` command to the application while the `GO` is still processing. If this command is received at any other time, it is ignored completely with no response. This is because the debugger may send the command but the application finish its `GO` before receiving it. The stop will then be the next command the application finds. If it made some kind of response to it, the debugger sends command, application responds format we be broken.

### **STEP**

One statement is executed. The application always responds with:

```
STEP COMPLETE
STEP COMPLETE WITH ERROR
```

STEP COMPLETE WITH TRAPPED ERROR

In the case of a single step any of the returns indicates the statement is finished. Step means do one statement, regardless of whether or not it resulted in an error. The return lets the debugger know if an error was encountered.

### **TEST BREAKPOINT filename:line-number**

Tests to see if the given filename and line number is a valid breakpoint. The applications responds with:

```
IS BREAKPOINT
NOT BREAKPOINT
```

Note: this does not mean that the line has been flagged with the `BREAKPOINT` command. It tests if the script could possibly break at this line, i.e. if this line is one that can support a breakpoint.

### **EVAL expression**

The expression is evaluated by the application. It responds with:

```
EVAL SUCCEEDED
EVAL FAILED
```

The second response indicating an error return. In either case, the expression's value is retrieved using the `GET` command described below.

### **GET object index**

Get any variable on the application. The object can be:

```
GLOBAL
LOCAL
THIS
FUNCTION
EVAL_RESULT
#object-id
```

The object id is returned when getting variables and allows recursing of variables. The index, which does not apply to `EVAL_RESULT` and should not be included in this case, indicates which member of the object is being queried.

The values returned for `GLOBAL` are the global variables. `LOCAL` is the local variables. `THIS` is the current `this` object. `FUNCTION` does not take an index and is the name of the executing function. `EVAL_RESULT` also does not take an index and is the result of the last `EVAL` command. Errors are also stored here.

Results from the application include:

```
NO SUCH MEMBER
```

If the index is beyond the number of members

```
NULL
UNDEFINED
BOOL true or false
NUMBER number
```

The given member is of the given type and value.

```
STRING LENGTH string-length-in-bytes
string data
END STRING
```

If the value is a string.

```
UNICODE STRING LENGTH string-length-in-bytes
string data
END STRING
```

To pass a unicode string, length will be twice number of chars. Unicode chars are passed in little endian byte order.

```
OBJECT #object-id
```

If the value is another object.

### **STRING object index**

This works just like `GET`, but the value is converted to a string. This is useful for output. For instance, errors result in error objects. The debugger may not be interested in that object and may just want to put an error message to the screen. This allows that to occur easily.

### **VARNAME object index**

Works much like `STRING`, but the returned string is not the value of the members, but the member's name. Before the string is returned, the attributes of the variable are returned on their own line, in brackets. If the variable has no attributes set, the brackets will be empty. Otherwise, they will be a comma-separated list of the attributes. The possibilities are: `DontEnum`, `DontDelete`, `ReadOnly`, `ImplicitThis`, `ImplicitParents`.

### **STACK index**

Set the call stack index to the given value. 0 is the normal value indicating the current top of the call stack, i.e. what is executing. 1 is the function that called it, etc. If it is out of range, the result will be a `DENIED`, else it will be:

```
STACK SET TO index
```

Once the call stack index is changed, all of the reporting functions are going to return values relative to that index. For instance, `REPORT` gives the file/line number of the function in that index, `GET LOCAL` refers to the local variables of that function, and so forth.

### **RELEASE #object-id**

Used after a `GET` that returned an object identifier to indicate no longer interested in the object and can release that identifier. The application response is:

```
OBJECT RELEASED
OBJECT NOT FOUND
```

The debugger must release object identifiers after it uses them to query subobjects, else it will lock a lot of memory on an application and can alter the behavior of the application. You are not allowed to have any pending locks when you issue a `GO` or `STEP` command, and if you do that command will be `DENIED` with a message to this effect.

### **QUIT**

Use to indicate to the application that the connection is to be closed.

# Extlibs

Extlibs, or external libraries, are a method to include wrapper libraries in an external object, a dynamic link library or shared object depending on the system. These extlibs are only loaded when the script writer needs them, via the `#link` directive. In addition, extlibs allow an application to include additional wrapper libraries for its scripts that were not available when the application was released.

ScriptEase releases for each operating system include sample extlibs as well as the source code for all extlibs shipped with that version. The source code is found in subdirectories of the `src\lib` directory, while the projects or makefiles are found in subdirectories of the `extlibs` directory.

## BUILDING AN EXTLIB

To build an extlib for your system, you should set up your compiler to build a new dll or shared object. The extlibs shipped with the ScriptEase ISDK have their appropriate makefiles/projects for you to look at if you have any questions. Include the base directory of the ScriptEase distribution as an include path in addition to any include paths needed for your extlib's source files. Finally, link with the extlib library found in `lib/extlibs/<system>/libsee501ar.a`. The format of this file and its name is consistent with the format and name for the `core` and `library` versions described in the chapter on "[Integration Into Your C/C++ Application](#)".

The source code for the extlib itself is not an application. Instead you implement a few functions needed by the extlib framework provided in `src\lib\common\selink.c`. These functions allow your extlib to initialize itself on load. Usually, you will use the load as an opportunity to add new wrapper function tables to the context corresponding to the functionality of the extlib you are implementing. Therefore, in addition to the stock routines to be described next, you will have a number of wrapper functions implemented in the normal way as described in the chapter on "[Wrapper functions](#)".

For most operating systems, you need only define a single function in your extlib implementation. That function is defined as follows:

```
SE_CALLBACK( sebool )
seExtensionLoadFunc(secontext se);
```

The function adds its function libraries to the context using `seAddLibTable()` and does any other initialization. It return `TRUE` to indicate success. A `FALSE` return will cause the extension library load to fail.

The exception is Netware™. Because of the way Netware™ works, it must define two additional functions. The following code gives an example of these functions for the `sesock` extlib:

```
#if defined(__JSE_NWNLM__)

#ifdef _cplusplus
extern "C" {
#endif

JSEEXTNSN_EXPORT(long)
```

```

sesockjseExtensionVer(secontext se)
{
    return seExtensionVer(se);
}

JSEEXTNSN_EXPORT(sebool)
sesockjseLoadExtension(secontext se)
{
    return seLoadExtension(se);
}

#ifdef _cplusplus
}
#endif

#endif

```

The only change you must make is in the name of the two routines. `sesock` must be replaced with the name of your extlib. It must correspond exactly to the `.nlm` executable to which the extlib is built; you cannot rename NLM extlibs. If the name of the `.nlm` does not correspond to the name of these two routines, the extlib will fail to load.

# Core Customization Topics

The ScriptEase core is highly customizable to suit the needs of a variety of scripted applications. This chapter described the customization options available. All of these options are determined by compile-time `#defines`. Once the options are set, the ScriptEase core must be recompiled to reflect these options. As a result, only customers who have purchased ScriptEase and thus have the source code to the ScriptEase core can benefit from customizing the core.

The `jseopt.h` file found in the distribution contains the same documentation as is here. For each define, it starts either on or off (off being commented out). Read through this chapter and the `jseopt.h` file and change the state of any of the options you like. Below, each option is listed as either on or off, reflecting the default state.

---

## CHARACTER SET CUSTOMIZATIONS

Choose a character set. These are exclusive options, uncomment the define for the character type you wish to use. `JSE_ASCII` stands for an ASCII character set build and is the default. `JSE_UNICODE` and `JSE_MBCS` (multibyte character set builds) are the other two possibilities.

### **JSE\_ASCII** (on)

Select an ASCII build explicitly, the default.

### **JSE\_UNICODE** (off)

Build using Unicode instead of ASCII.

### **JSE\_MBCS** (off)

Build using MBCS instead of ASCII.

### **JSE\_USER\_DEFINED\_MBCS** (off)

ScriptEase allows an MBCS build to specify the functions for reading and writing characters into strings. By default, the standard system MBCS routines are used to do so. Turn this define on if using an MBCS build to utilize your own routines.

---

## CORE CUSTOMIZATION

The following options modify the internals of the ScriptEase core, and are used mostly to balance performance and memory use.

### **JSE\_MIN\_MEMORY** (off for most systems)

The most important definition related to memory use is `JSE_MIN_MEMORY`. This value determines the default values are a number of other defines.

`JSE_MIN_MEMORY` turned on indicates that the values that conserve memory are selected in each case. Generally, you can simply turn on this define for small memory systems rather than picking and choosing among the options. By default,

this define is off for most systems. The particular systems it is normally on for are DOS 16-bit, WINCE, Blackberry, and Palm.

## **JSE\_MULTIPLE\_GLOBAL** (on)

By default, ScriptEase remembers the global object in effect when each function is created and runs each function under its original global object. This flag can be used to turn off this behavior.

## **JSE\_HASH\_SIZE** (256)

Determines the number of slots in the string hash table. This table is used to store all member names. Increasing the size will improve performance slightly at the cost of more memory.

## **JSE\_ONE\_STRING\_TABLE** (off)

Normally, each context has its own string table. Turning on this define makes a single string table be used. A single string table is not compatible with a multithreaded application using more than one context.

## **JSE\_INFREQUENT\_COUNT** (5000)

ScriptEase normally calls an application's continue function after each script statement is executed. `seEval` provides the option to call less frequently. This define indicates how many statements are to be processed between each call to the continue function.

## **JSE\_INTERNAL\_PROFILING** (off)

ScriptEase can keep a timing count for time spent in various areas of the ScriptEase engine and the user's application. Normally, this option is turned off.

## **JSE\_GET\_RESOURCE** (off)

Normally, all resources (text error messages for instance) have their text stored with the application. If this option is on, rather than using the stored text, the application's `seGetResourceFunc` callback is used to retrieve the text for any resource.

## **JSE\_SHORT\_RESOURCE** (off)

When this define is turned on, all resource strings retain only their identifier. If you provide an `seGetResourceFunc`, those identifiers will be turned into real strings using it. If you do not, error messages and other resources will contain only the error number and no message.

## **JSE\_TRAP\_NOWHERE** (off)

Normally, when an API function tries to get an object that doesn't exist or can't be converted to an object, the engine returns `SE_NOWHERE`. This allows your application to use that object without error checking the result. However, you may instead wish to check all your results for errors and ensure that this object is never used. Turning on this define, which defaults to being off, causes an error if `SE_NOWHERE` is ever tried to be used.

## **JSE\_INLINES** (on, off if `JSE_MIN_MEMORY` is defined)

In the ScriptEase core, a number of functions are expanded inline to improve speed. These functions take up considerable code space. The define `JSE_INLINES` defaults to on only if `JSE_MIN_MEMORY` is not defined, inlining only when memory conservation is not an issue.

## **JSE\_PEEPHOLE\_OPTIMIZER** (on)

The peephole optimizer is run on the bytecodes ScriptEase produces for each function, transforming certain inefficient common sequences into more efficient ones. It speeds up programs and shrinks the resulting bytecodes. The only disadvantage is an increase in compilation time, which may outweigh speed performance if scripts consist of a number of quick and tiny functions.

## **JSE\_CACHE\_GLOBAL\_VARS** (on)

When on, ScriptEase maintains a cache of recently-accessed global variables, speeding access to them in many cases. However, without certain transformations done by the peephole optimizer, the global variable cache can be too aggressive and return the wrong result at times. Therefore, you should only use the global cache if the peephole optimizer is turned on, as is the default.

## **JSE\_GLOBAL\_CACHE\_SIZE** (10)

By default, the number of global variables retained in the cache is 10. Increasing the size of the cache could increase cache hits, but the time to look through them may slow misses. Our internal testing indicates the value of 10 is about optimal. Global caching must be enabled for this define to be useful.

## **JSE\_COMPACT\_LIBFUNCS** (off)

By default, this is on. ScriptEase stores wrapper functions in a minimal way, expanding them on first use. Since most applications include a large number of wrapper functions such as the standard ECMA library, and scripts use only a fraction of them, this setting conserves a lot of memory. There doesn't seem to be a good reason to turn it off, but the option exists nonetheless.

## **JSE\_ALIGN\_DATA** (off)

Some systems require structures to have their members aligned and thus this flag is on for them. It is off for most systems. By not defining it, the default, ScriptEase chooses the right value for your system. However, you can always force it to be on. This will always work, but use more memory if it did not need to be used.

## **JSE\_REFCOUNT** (off)

## **JSE\_GC** (on)

Normally, `JSE_GC` is on meaning ScriptEase reclaims memory by garbage collecting. If `JSE_GC` is off and `JSE_REFCOUNT` is on, ScriptEase uses a reference counting scheme. This takes more memory and is slower, but it frees objects as soon as they become unused. It cannot detect cyclic loops. If both are on, reference counting is supplemented via garbage collection to find cyclic loops.

`JSE_GC` is noticeably quicker and less memory-hungry than is `JSE_REFCOUNT`. Garbage collection passes are quick as well, on the order of tenths of a millisecond on a typical machine. Therefore, the main benefit of `JSE_REFCOUNT` is to find objects that have become freed as soon as they have done so. However, in most applications, you are better off leaving `JSE_GC` on and forcing a garbage collection (by calling `seGarbageCollect`) at any critical point that you need to ensure unused objects are freed.

By default, `JSE_GC` is on and `JSE_REFCOUNT` is off. Note that either one or both of them may be defined. However, at least one of the two must be defined. If both are turned off, `JSE_GC` will be selected automatically.

### **SE\_OBJ\_POOL\_SIZE** (1024, 128 if `JSE_MIN_MEMORY` is on)

ScriptEase maintains a pool of objects for its needs so that it doesn't need to allocate and free objects to the system often. The bigger the pool, the less system allocation is required at the expense of more memory used by the pool. Also, the emptying of the pool triggers garbage collection, so the bigger the pool, the longer ScriptEase can go between garbage collections.

Because emptying a pool triggers garbage collection, reducing the pool sizes below the value for a `JSE_MIN_MEMORY` build will cause ScriptEase's execution speed to slow drastically due to constant collection while freeing up very little memory. It is advised that you treat 128 as the minimum for this define.

### **SE\_MEM\_POOL\_SIZE** (1024, 128 if `JSE_MIN_MEMORY` is on)

The members of an object are stored in a separate structure that works exactly like `SE_OBJ_POOL_SIZE`. Since each object requires one descriptor for its members, it is usually best to keep these two pool sizes identical.

### **SE\_STRING\_POOL\_SIZE** (512, 64 if `JSE_MIN_MEMORY` is on)

Each string in a script requires a string descriptor. These are pooled just like object and member descriptors. This define determines the size of that pool. Like the other pools, it has default sizes depending on the min-memory setting. With min-memory on, it is 64 entries otherwise it is 512 entries.

### **JSE\_STRINGS\_COLLECT** (1000000, 100000 if `JSE_MIN_MEMORY` is on)

ScriptEase's GC engine triggers collection whenever its internal pools (of objects) are exhausted and refills them. However, for string data, ScriptEase instead collects after each set number of bytes of strings are allocated. This option allows you to change how many bytes trigger a collection. The default is 100000 for min-memory, 1000000 for bigger systems.

### **JSE\_PACK\_OBJECTS** (off, on if `JSE_MIN_MEMORY` is on)

Objects are packed to use the minimum memory. This setting is incompatible with `JSE_ALIGN_DATA`. Turning this on saves significant memory, but on many systems brings an equally significant loss in performance when dealing with objects.

### **JSE\_PACK\_SECODES** (off, on if `JSE_MIN_MEMORY` is on)

The bytecodes are packed, conserving memory at the cost of execution speed. Bytecodes can only be run on a ScriptEase application with the same setting for this define as the one that created the bytecodes.

### **JSE\_POOL\_STRINGDATA** (on, off if **JSE\_MIN\_MEMORY** is on)

ScriptEase always pools string descriptors. If this define is on, ScriptEase also retains the string data space to be reused when the string descriptor is next used. This allows faster string manipulations but uses up more memory. By default, it is on only if not using a min memory setting.

### **JSE\_PER\_OBJECT\_CACHE** (on, off if **JSE\_MIN\_MEMORY** is on)

Each object caches the last member in it that was accessed. In many programs, this improves performance. Turning it off reduces memory requirements for objects slightly at the cost of performance.

### **JSE\_PER\_OBJECT\_MISS\_CACHE** (on, off if **JSE\_MIN\_MEMORY** is on)

Objects store the last member searched for that the object did not have. This speeds up searching for global variables in which a chain of objects is searched for a particular member, often missing each time for the first few objects in the chain. By default, non-min memory builds have a per-object miss cache.

### **SE\_APISTRING\_POOL\_SIZE** (5)

The ScriptEase API uses a string locking structure when strings are returned to the user. Like many other internal structures, this structure is pooled in order to reduce calls to the memory allocation routines. However, this pool is very small; typically only one or a few strings will be allocated at once, so a large pool is unnecessary.

### **SE\_APIVARNAME\_POOL\_SIZE** (5)

Varname structures are used by the API for internalized variable names. Like string locking structures, they are needed only when the user has an internal string locked. While many programs will lock a number of such names, they remain locked for the life of the program. Typically, only one or a few names are locked and then freed at a time.

### **SE\_STACK\_SIZE** (2048, 512 if **JSE\_MIN\_MEMORY** is on)

ScriptEase uses an internal stack for resolving function calls and evaluating expressions. Each function call needs a few entries for overhead plus one entry per parameter passed to it and per local variable it allocates. The default size of this stack is 2048 entries, enough to recurse typical functions to a depth in the hundreds. 512 entries is allocated for a min-memory build.

### **SE\_MAX\_STACK\_INFO\_DEPTH** (64)

The **SE\_STACK\_INFO** stack objects allow the API user to examine the call stack of a running script. This macro determines the maximum depth that can be examined. Each depth only requires one pointer (usually four bytes), so

increasing the max depth isn't costly. However, it is unlikely any program will need more depth.

---

## FEATURE CUSTOMIZATION

The following options all turn on or off certain JavaScript features. These features are part of standard ECMAScript, but you may choose to disable certain features to conserve space for low-memory systems.

### **JSE\_COMPILER** (on)

The ScriptEase compiler is necessary to run script code. With the compiler turned off, your application will only be able to run precompiled scripts. The JavaScript `eval` function relies on the compiler being enabled. The compiler is on by default.

### **JSE\_TOOLKIT\_APPSOURCE** (on)

This define determines whether the `seGetSourceFunc` is to be used by the compiler when it reads text. By default, it is on. This define is only applicable for the compiler.

### **JSE\_SAVE\_FUNCTION\_TEXT** (on, off if **JSE\_MIN\_MEMORY** is on or **JSE\_COMPILER** is off)

ScriptEase needs to retain information about the source of script functions to allow the `toSource` call to turn those functions back into the source they came from. This option tells it to do so.

### **JSE\_PROTOTYPES** (on)

Allows the JavaScript prototype-related features. JavaScript is heavily dependent on prototypes and many of its features are built on top of them. Turning this off is probably a bad idea.

### **JSE\_ALWAYS\_IMPLICIT\_THIS** (off)

With this flag set, the `this` variable is always searched as part of the scope chain. Normally, the user must set the `SE_IMPLICIT_THIS` flag for each function individually. Turning this compile-time option on will make that the default for all functions.

### **JSE\_ALWAYS\_IMPLICIT\_PARENTS** (off)

Similar to `JSE_ALWAYS_IMPLICIT_THIS`, this flag will turn on implicit parents for every function, causing the engine to search the `__parent__` member of the `this` variable when resolving variable names.

### **JSE\_FUNCTION\_ARGUMENTS** (on)

When calling a function, some older scripts use the `<function>.arguments` syntax rather than just using `arguments`. This behavior is rare but by default we support it.

### **JSE\_AUTO\_OBJECT** (off)

An older ScriptEase behavior, undefined variables are automatically converted to an object when used as an object.

## **JSE\_REGEX\_LITERALS** (on)

By default, JavaScript regular expression literals are allowed. They are a standard part of JavaScript. However, if you turn off the regular expression portion of the ECMA library, you should turn this off as well. The regular expression code is large and is commonly left out of applications running in tight memory.

## **JSE\_FUNCTION\_LENGTHS** (on)

Each function gets a `.length` property, the number of parameters it takes. Turning this off will conserve memory slightly. Because it is a JavaScript feature, this option is on by default.

## **JSE\_HTML\_COMMENT\_STYLE** (off)

If this option is turned on, HTML-style comments will be accepted (i.e. `<!-- ... -->`).

## **SE\_ECMA\_RETURNS** (on)

If no value is explicitly `returned` from the body of a script, the last expression evaluated is returned implicitly. Normally, each expression evaluated has its result preserved against the possibility it is the last expression evaluated and thus needs to be returned. If this flag is turned off, the last expression is determined by an alternate algorithm. While this algorithm is faster, some cases will confuse the algorithm and cause an improper value to be returned.

---

# **SCRIPTease FEATURE CUSTOMIZATION**

The following options are similar to Feature Customization, but they modify ScriptEase-only features.

## **JSE\_TOKENSRC** (on)

Allows ScriptEase to produce tokens. You can use `sePrecompile` only if this define is on. The compiler portion of ScriptEase must also be turned on.

## **JSE\_TOKENDST** (on)

Allows ScriptEase to run precompiled scripts. This option is necessary to pass precompiled scripts to `seEval`.

## **JSE\_DYNAMIC\_CALLBACKS** (on)

By default, objects can be given a callback table to implement their `get`, `put`, `delete`, and other operators using the `seSetCallbacks` API call. Turning off this option removes that capability.

## **JSE\_OPERATOR\_OVERLOADING** (on)

Operator overloading is one of the object callbacks. It can be individually turned off.

## **JSE\_ENABLE\_DYNAMETH** (off)

Object callbacks are normally not recursive, they are shut off while active. In other words, if you are implementing the dynamic get for an object and you try to get a member of that object, you won't be stuck in an infinite loop; rather that get will get the property from the internal ScriptEase store. It is possible that a particular application does want the recursive behavior. This option makes available the `seEnableDynamicMethod` API call, which allows a particular dynamic method to be turned back on.

## **JSE\_GETFILENAMELIST** (off)

If your application does not need to use the `SE_FILENAMES` object, you can turn it off and save the code and runtime space associated with storing these filenames.

## **JSE\_BREAKPOINT\_TEST** (off)

If your application does not need to use the `seIsBreakpoint` call, you can get rid of it to save some space. The ScriptEase debugger requires this call to operate.

## **JSE\_TASK\_SCHEDULER** (on)

ScriptEase supports the concept of fibers. Turning off this option will turn off the `seCreateFiber` API call as well as the `SE_YIELD` and `SE_SUSPEND` members of the `SE_RETURN` object.

## **JSE\_LINK** (on)

Turns on the `#link` directive.

## **JSE\_INCLUDE** (on)

Turns on the `#include` directive.

## **JSE\_DEFINE** (on)

Turns on the `#define` directive.

## **JSE\_CONDITIONAL\_COMPILE** (on)

Turns on the `#if`, `#elif`, `#else`, `#ifdef`, and `#ifndef` directives.

## **JSE\_SECUREJSE** (on)

By default, the ScriptEase security model is on. If you are not intending to use security, you can turn it off to save space.

## **JSE\_NUMTOSTRING\_ROUNDING** (on)

When turning a number into a string, ScriptEase performs rounding. This is an attempt to counteract the fact that certain numbers cannot be stored exactly using the C `double`, and they look odd when printed out. If this option is turned off, numbers will be printed out exactly as they are stored.

## **JSE\_MAIN\_ARGC\_ARGV** (on)

ScriptEase has the legacy option to treat a function named `main` as special, auto-calling it like C. The `SE_CALL_MAIN` option to `seEval` causes this to be done. By default, this is available. If you have no interest in this option, you can get rid of it completely and save some code space.

## **JSE\_TOSOURCE** (on)

ScriptEase provides a number of helper functions that ease turning an object class into its appropriate source code, to implement the `toSource` method. Many of the standard ECMA objects we provide rely on this code. Turn it off only if you are not using the ECMA objects and do not need the helper routines for your own functions.

## **JSE\_NAMED\_PARAMS** (on)

ScriptEase allows passing parameters by name, such as calling a function like `foo(a:10,b:"blah");`. Turn off this option to remove this capability.

## **JSE\_TIMEZONE\_GLOBAL** (off)

Some implementations do not have knowledge of the local machines timezone. In this case, you can turn on this define, and fill in this global variable with the information:

```
extern slong jse_minutes_from_gmtime;
```

## **JSE\_TOLOCALEDATE\_FUNCTION** (off)

The optional `toLocaleDate` method of the the `Date` object is off by default.

## **JSE\_MILLENIUM** (off)

Several JavaScript date functions deal with 2-digit dates, assumed to be from the 20th century. Because such functions are not year-2000 compatible, they are turned off by default.

## **JSE\_NO\_AUTO\_INIT** (off)

If this option is on, `extlibs` when loading will not automatically add their functions to the current global object. Instead, you'll have to explicitly call the `LoadLibrary_XXX` function in the `extlib`. This define is only applicable to building `extlibs`.

## **JSE\_BROWSEROBJECTS** (off)

Nombas provides a framework for implementing the browser objects such as `window`, `document`, etc. If you turn on this option, they will be added. You will need to implement a number of routines to get these to work. See the files in `src/browser` for documentation.

## **JSE\_THREADSAFE\_POSIX\_CRTL** (off)

This option causes ScriptEase to use threadsafe versions of the standard C library routines that use internal buffers.

## **JSE\_PREEMPTIVE\_THREADS** (on)

Determine if you intend to use multiple threads with ScriptEase. Generally, it is safe to leave this define on as even if you are not using multiple threads, it doesn't hurt.

## **SE\_SHARED\_OBJECTS** (on)

Activates the API function `seShareReadObject` which allows objects to be shared among threads.

## **JSE\_PASSBYREF** (on)

ScriptEase supports the passing of parameters to script functions by reference by using the `&` operator and to wrapper functions by using the `SE_BYREF` flag. This define turns the support on, which is the default.

---

# **DEBUGGING CUSTOMIZATION**

These options affect debugging and the level of internal checks ScriptEase performs.

## **NDEBUG**

This is not usually defined in the `jseopt.h` file, but rather by your compiler depending on if you are building a release or debug version. However, it is a very important define which ScriptEase uses extensively. When `NDEBUG` is not defined (i.e. a debug build), ScriptEase does a significant amount of internal checking for any bugs, either errors in ScriptEase itself or errors in an application's use of the API. You should do all development without the `NDEBUG` flag as you can find many bugs this way. When you are ready to release, turn `NDEBUG` back on for the fastest possible code.

## **JSE\_MEM\_DEBUG** (on if `NDEBUG` not defined)

In debug mode (i.e. `NDEBUG` not defined), by default ScriptEase adds extensive tests on top of the memory allocation system. These tests will locate unfreed memory, will fill freed memory with garbage, will test for writing past either end of a block of memory, and several other memory-related tests. It is usually best to leave this define on for your debug builds.

## **JSE\_SLOW\_MEM\_ALLOC** (off)

Some systems allocate memory very slowly. ScriptEase can emulate slow memory routines to help reproduce these problems.

## **JSE\_ENFORCE\_MEMCHECK** (on)

By default ScriptEase will cause calls to the standard allocation routines to be marked as errors. This is because ScriptEase always uses its own allocation routines. In non-`JSE_MEM_DEBUG` mode, these routines just internally use the standard allocation routines. If you need to call the standard allocation routines directly, turn this define off.

## **JSE\_TRACK\_MEMUSE** (off)

Enables a more detailed memory tracking system which keeps track of the number of allocations, maximum allocated at any point, and total allocated for

every structure within the ScriptEase engine. It is primarily used only for internal debugging and to detect excessive memory waste.

## **JSE\_TRACK\_OBJECT\_USE** (off)

This is an internal routine that keeps track of how many times object members are accessed, and whether they are found in the cache or needed to be looked up. It is used primarily to optimize the object cache and detect bottlenecks in member lookup.

## **JSE\_NEVER\_FREE** (off)

An extreme bug-detection setting used for self-debugging by the ScriptEase engine. When on, the garbage collector never frees unused memory. It does fill the memory with a particular byte value when no longer used. This will cause ScriptEase to use enormous memory, but is useful to isolate internal garbage-collection related bugs.

## **JSE\_DONT\_POOL** (off)

Another garbage collection setting. ScriptEase normally maintains a pool of objects and reuses them whenever possible. In this mode, all memory is returned to the system when not in use and reallocated when needed. This is a very slow mode designed to shake out any internal bugs.

## **JSE\_ALWAYS\_COLLECT** (off)

The garbage collector normally runs only when ScriptEase detects it is low on memory. If this is on, the garbage collector is run any time it could possibly be run, regardless of memory. This is an important setting to self-diagnose ScriptEase core bugs, but is very slow. 'very slow' means that - VERY slow.

## **JSE\_PSEUDO\_PALMOS** (off)

This define turns on many of the 'weird' settings necessary to get ScriptEase to run on the Palm. Since the Palm is very difficult to debug on, it is useful to debug these palm-specific oddities on a larger system.

---

# **FLOATING POINT CUSTOMIZATION**

The ECMAScript standard specifies that an ECMAScript number match the double-precision 64-bit format IEEE 754 values. In most compilers this is represented as `double`, and this is the default for the ScriptEase engine. However, there may be situations where a different meaning for “number” may be more appropriate, such as when a `double` is too large or requires too much processing time (e.g., small systems without floating-point coprocessors), or when floating-point numbers are not needed at all.

Within the ScriptEase:ISDK/C the exact type for an ECMAScript number is never hard coded, but is instead defined by the `senumber` type. By default `senumber` is defined the same as the C `double` type, but that may be changed to any definition that is better suited to your system. The file `src/include/sefp.h` defines defaults for this value for floating-point and integer-only builds. You may choose to modify the type of `senumber` to be

anything else, such as a `float`, an `integer`, a packed value, a string, or even a structure (as is found in the `fpemul` sample).

## **JSE\_FLOATING\_POINT** (on)

This value defines whether the ScriptEase interpreter and libraries will support floating-point operations. If this is not defined then the engine will only support integers, and any use of a floating-point number or operation will result in an exception (e.g. `pi=3.1415`, `Math.cos()`, `0.0`). An application for a small device may run much smaller and faster when `JSE_FLOATING_POINT` is not defined if floating-point math is not needed.

## **JSE\_FP\_EMULATOR** (off)

You can completely redefine all of the floating-point types and operations by compiling with `JSE_FP_EMULATOR` defined. If this flag is defined, then you must implement, through macros or function calls, all of the basic and extended math operations. Even such a simple operations as adding two numbers or converting a number to an integer must be defined by your macros and functions. Those macros and functions are all defined in the file `src/include/sefp.h`.

One example has been provided for using `JSE_FP_EMULATOR`. If the tester (`tests/testers/config/fpemul.h`) header file is used, it defines `JSE_FP_EMULATOR` and includes a sample implementation of all the math routines as found in `src/app/fpemul.*`. This example is built for systems that need floating-point support but which have very slow FP emulation. The goal is to make numbers be kept as integers as long as possible and only converted to floats when they cannot be represented accurately as integers—the resulting code matches the ECMAScript specification but with optimal speed on a slow-FP system. Note that this is just one sample implementation; different platforms will have different schemes for FP emulation.

---

# **MEMORY EXTENSIONS**

The ideal computer for a high-level scripting language would have unlimited fast RAM but many platforms are a long way from this ideal. For example, some systems have a relatively small amount of heap memory and a larger switched area for external RAM storage; some systems have relatively small memory but a huge amount of disk storage; some systems go through periodic heap compression and so allocated memory must be allowed to move; some systems have memory that is really a database; some systems support fast reads on memory but slower writes; and so on...

## **JSE\_MEMEXT\_MEMBERS** (off)

## **JSE\_MEMEXT\_OBJECTS** (off)

## **JSE\_MEMEXT\_SECODES** (off)

## **JSE\_MEMEXT\_STRINGS** (off)

## **JSE\_MEMEXT\_READONLY** (off)

These flags define whether the memory extensions will be used. There are four types of data for which the memory extensions are used: objects, members of objects, strings, and secodes (which are the virtual-machine bytecodes associated with each script function). Usually you would define all or none of these, but you may want to turn some on or some off depending on the type of scripts you'll be running and the balance needed between memory use and performance (for example, for the function overlay technique described below you may choose to only implement `JSE_MEMEXT_SECODES`).

`JSE_MEMEXT_READONLY` is defined for systems that distinguish between memory that is read-only and memory that is read-write. If it is just as fast to use writable memory as it is to use read-only memory, then leave this flag off. If this flag is defined then the engine will access memory in read-only mode as much as possible, and so improve overall performance.

The memory-extension routines in the ScriptEase engine use a caching algorithm to balance memory use versus performance, so that memory handles that are more likely to be used soon are maintained in a cache. These cache sizes can be adjusted by overwriting the compile-time parameters in the `src/include/sememext.h` file.

The PalmOS version of SE:ISDK/C makes extensive use of memory extensions because the PalmOS has relatively little heap space, but much more long-term storage. Another interesting example of the use of memory extensions is to implement a function-overlaying system. As one example, a systems may have a small amount of RAM and much more disk space. As the scripting functionality expands on the system (because it is much easier to implement new functionality via scripts) memory may run short. One solution is to enable `JSE_MEMEXT_SECODES` and `JSE_MEMEXT_READONLY` so that the virtual-machine bytecodes for functions are cached to the hard disk, with seldom-used functions taking up no memory unless they are needed.

There are many more situations and sample implementations for which memory extensions are needed. For more information see the comments in the `src/include/sememext.h` file about typedefs and macros that you must define to use memory extensions. Also see two sample implementations included with the SDK in the `tests/testers` subdirectory: `mmemext.h` and `mmemext.c` demonstrate handles to externally allocated memory, and `fmemext.h` and `fmemext.c` demonstrate using file handles as memory extensions. These two samples are both more useful for education and testing than they are useful for real world situations.

# Fibers and Threads

Each `secontext` can be used by only a single thread at one time. If you want to run multiple scripts simultaneously in a multithreaded application, you need to create one `secontext` using `seCreateContext` per thread. You can in fact create more than one `secontext` per thread if you like.

Each context contains a copy of much of the same data. Namely, each context will initialize the standard function libraries into its global object in order to allow its scripts to see them. In addition, each context keeps a pool of various kinds of memory available in order to increase performance. As a result, each context has significant overhead of memory. Fibers exist to help alleviate this problem.

Fibers are like sibling contexts. Each fiber in the same group has access to the same variables, uses the same pools of memory, and so forth. Therefore the overhead described exists only once even when a large number of fibers exist in the same group. However, fibers are not a replacement for separate contexts in multiple threads. All fibers in the same group are considered one context, so they can only be used by a single thread and only one fiber can be active at once. You can use fibers to cooperatively multitask scripts but since only one fiber can be run at once, fibers do not take advantage of multiple processors. If your machine has multiple processors, and you would like to run multiple scripts taking advantage of all the processors, you must use full contexts not fibers.

Fibers are created using the ScriptEase `seCreateFiber` API call. You pass as a parameter an existing context. The new fiber is created as part of the same fiber group the existing context is part of. You create the first context using `seCreateContext` then create any number of fiber siblings using `seCreateFiber`. When you are done, you have a number of related contexts, each which can run its own script. However, all of the contexts share a single global object. You can change the global object in any of the fibers, but the intent of the fibers is to conserve memory so sharing the global object is the norm.

---

## USING SE\_START

As was mentioned, each fiber group has the limitation that only one of the fibers can be running at the same time. If you use `seEval` to evaluate a script in one fiber, you must wait for it to complete before evaluating another script in a different fiber. To get around this limitation, `seEval` has the `SE_START` flag option.

`SE_START` initializes an eval and then returns. Successive lines of the script are run using the ScriptEase `seExec` API call. Using this method, when you initialize each fiber you begin the script it is to run using `seEval` and `SE_START`, which then returns to you quickly. You do the same for each fiber. Now you can execute a single line of each script using `seExec`. Typically, you keep evaluating one line on each fiber in a round-robin fashion in this way. As each fiber completes its task, it is removed from the list of fibers to execute in this way. New fibers can be created and added into the list easily.

## GLOBAL MANIPULATION

Although the intent of fibers is to conserve memory by sharing overhead, often each fiber should still be independent. For instance, you may not want them to share global variables. This is easy to accomplish. After you create the initial context and set up the libraries in it using `seCreateContext`, you preserve that global object. Then for each fiber (including the original context returned by `seCreateContext`), you give it a new global object with its `_prototype` pointing to the preserved global object. Thus, all new variables created in a fiber will be created in its private global object, yet it still can refer via the global's prototype to the original global object which contains all the standard function libraries.

Here is a short example ScriptEase API application that creates several fibers and runs them all.

```
#define MAX_FIBERS 5

/* -----
 * Error handler
 * ----- */

SE_CALLBACK( void )
my_error_printer(secontext se,seconstcharptr text)
{
    printf_sechar(UNISTR("Error encountered: %s\n"),text);
}

/* A wrapper function to write out a string. It converts
 * whatever argument it is given to a string then writes it
 * to the terminal using 'printf'. The user would use it like
 * this:
 *
 *     StringOut("Hello, world!");
 */

/* -----
 * Text output
 * ----- */

SE_CALLBACK( void )
StringOut(secontext se,sememcount argc)
{
    sememcount i;
    seconstcharptr text;

    for( i=0;i<argc;i++ )
    {
        /* Get each successive argument and print them
         */
        text = seGetString(se, SE_ARGS,SE_NUM(i), NULL);
        printf_sechar(UNISTR("%s\n"),text);
    }
}

SE_BEGIN_LIB_TABLE( SampleFunctionList )
    SE_FUNCTION( "StringOut",    StringOut,    1, -1,
                SE_SECURE, SE_DONTENUM ),
SE_END_LIB_TABLE
```

```

void
add_fiber(secontext se,secontext *table,int *number,
          seobject glob)
{
    assert( (*number)<MAX_FIBERS );
    table[(*number)++] = se;

    /* give the fiber a private global */
    sePutObject(se,SE_GLOBAL,SE_VALUE,seMakeObject(se));
    /* but point back to shared so can see it */
    sePutObject(se,SE_GLOBAL,SE_STOCK(_prototype),glob);

    seEval(se,UNISTR("var a = 10;\nStringOut(a);\n"),SE_TEXT,
           NULL,NULL,SE_START,NULL);
}

void
remove_fiber(int num,secontext *table,int *number)
{
    assert( num<(*number) );

    /* we are done with the context */
    seDestroyContext(table[num]);

    /* remove it from the table */
    while( num<(*number)-1 )
    {
        table[num] = table[num+1];
        num++;
    }
    (*number)--;
}

void
main(int argc,char **argv)
{
    secontext se;
    secontext fibers[MAX_FIBERS];
    int fibers_used = 0;
    int fiber_current = 0;
    seobject shared_global;
    struct seContextParams params;

    seInitialize();

    memset(&params,0,sizeof(params));

    /* the print error function is the one required function. */
    params.sePrintErrorFunc = my_error_printer;

    /* initialize the main context */
    se = seCreateContext(&params,MY_JSE_USER_KEY);
    if( se==NULL )
    {
        printf_sechar(UNISTR("Invalid user key.\n"));
        exit(0);
    }

    shared_global = seGetObject(se,SE_GLOBAL,SE_VALUE);
}

```

```

/* add libraries so we have the StringOut function */
seAddLibTable(se, SampleFunctionList, NULL);

/* Add the original context to our fiber list. All contexts
 * including the parent will be treated identically
 */
add_fiber(se, fibers, &fibers_used, shared_global);

/* Create some more fibers. All are added to one big
 * pool.
 */
while( fibers_used < MAX_FIBERS )
    add_fiber(seCreateFiber(fibers[0]), fibers,
              &fibers_used, shared_global);

/* run the fibers until all have exited. For each fiber,
 * execute its next available statement using seExec().
 * Notice that an seEval using SE_START was started in
 * each fiber when it was added above. As each fiber
 * finishes its seEval(), we remove it from the fiber list.
 * We exit when all fibers are done.
 */
while( fibers_used > 0 )
{
    if( !seExec(fibers[fiber_current]) )
    {
        remove_fiber(fiber_current, fibers, &fibers_used);
        /* and continue using the fiber that fell into its
         * place
         */
    }
    else
    {
        fiber_current++;
    }
    if( fiber_current >= fibers_used ) fiber_current = 0;
}

/* Done with the sample, shut everything down. */
seTerminate();
}

```

---

## YIELDING AND SUSPENDING

At times, you may want to control the behavior of your fiber execution more than the simple control provided by executing a single statement at a time. Two methods are provided for you to do so. Both methods are invoked by a wrapper function to affect the execution of the fiber the wrapper functions is within.

When a wrapper function is ready to return, it sets up its value in the `SE_RETURN` object. Two members of the object, `SE_YIELD` and `SE_SUSPEND`, can likewise be set. Both are boolean members and are set `TRUE` to invoke their relevant behavior.

First is `SE_YIELD`. By yielding, the fiber ensures that the current `seExec` statement is immediately ended. Recall that the `SE_INFREQUENT_CONT` option to `seEval` means that several statements are executed for each call to `seExec`. If

a wrapper function yields, the `seExec` returns immediately. The return value for the wrapper function is still treated normally. The next time the fiber is executed using `seExec`, execution resumes with the code that called the wrapper function getting that value as the return.

The second option is `SE_SUSPEND`. Suspending functions is similar to yielding in that the calling `seExec` finishes immediately. However, the fiber is put into a suspended state. This means that further calls to `seExec` will immediately return without executing any code of the fiber. It is the job of your application to determine when the fiber is ready to be restored and remove its suspended state. This is done by assigning `FALSE` to the fiber's `SE_RETURN, SE_SUSPEND` member. After the suspend is removed, the application can also change the return value to be returned by the wrapper function before again executing any code. It does this by assigning the new value to the `SE_RETURN, SE_VALUE` member as normal. If it does not, the value returned by the wrapper function is used. This is useful if the value to be returned is unknown when the wrapper function suspended, perhaps that is why it needed to be suspended. Remember, though, that the `SE_RETURN, SE_VALUE` member is read-only as long as any of the boolean members are `TRUE` including the `SE_SUSPEND` member. You must turn the suspension off before you are allowed to write a new return value. Of course, you must do it also before you call `seExec` on the fiber after it is unsuspended.

---

## OTHER CONSIDERATIONS

It is important to understand that values returned from the ScriptEase API that follow the usual ScriptEase lifetime rules, such as `seobjects`, `sestrings`, and `seconstcharptrs`, are tied to the context they were created in. Any ScriptEase call that is passed that parameter must be passed the same context used to initially get that item. You cannot use an `seobject` created in one context with another, for instance.

Fibers are one exception. Fibers are designed to allow several contexts to share the same variables. All fibers in the same fiber group can share these items and use them in any context of the same fiber group. Items created in this way still must not be used with a context that is not part of the fiber group, however.

## READ-ONLY SHARED OBJECTS

ScriptEase supports one other sharing mechanism via the API call `seShareReadObject`. This call allows sharing ScriptEase objects across threads albeit with several limitations.

Object handles, i.e. `seobjects`, can be made sharable by passing them to the `seShareReadObject` api call. Once this is done, the handle can be used in any context and thus the object it refers to can be used in any context as well. Such handles no longer follow the usual ScriptEase lifetime rules. Such handles can only be created in the first ScriptEase context before any other contexts are created. These handles are valid until that context is destroyed.

A typical use for read-shared objects is to initialize a context using `seCreateContext` as normal. Whatever standard libraries are defined in your `jseopt.h` file are added to the context as normal. Any program-specific libraries are added in the context's `sePrepareContextFunc` callback. The

result is that all of the wrapper functions normally available to a script are initialized in that context's global object. That global object is made read-shared so that many new contexts can be created and share the same set of wrapper functions without having to reinitialize them in each context. This saves considerable startup time and memory for each new context created.

With this method, new contexts are created passing the `SE_OPT_NO_LIBRARIES` option to `seCreateContext`. This is because the new contexts will be sharing the old libraries and do not need their own copy of the libraries created. Likewise, these new contexts do not add program-specific libraries during their `sePrepareContextFunc` callback, instead using the copies created by the first context. The `_prototype` member of the global object of each new context is assigned with the shared global object thus allowing all new contexts to see and share the original libraries.

The ScriptEase sample `objshare` does exactly what is described above.

Read-shared objects are completely read-only as are their children. No changes at all can be made to them; they cannot get new members, have members deleted, alter member values, or be modified in any way. This applies in all contexts including the first context that originally created the object.

The shared objects are cleaned up when the context creating them, the first context, is destroyed. This means object destructors will be called and library termination routines invoked. The first context can only be destroyed if there are no other contexts sharing its objects. If you have shared any objects then a call to `seDestroyContext` on the first context will fail with an appropriate api error if there are any other contexts still undestroyed.

## SHARED SERVICES

It is common practice for function libraries to initialize and store data in the `SE_SERVICES` object for retrieval by their wrapper functions. However, the `SE_SERVICES` object is per-context. If you create and store information in that object, it will only be accessible from the context that created it. If the libraries are to be made read-shared, they cannot use this object to store data that should be accessible from any context using it.

Libraries that want to be able to be shared must use the `SE_SHARED_SERVICES` object to store any data that needs to be accessible from any context using the code. This object functions similarly to `SE_SERVICES`, you create members using a name that will not conflict with other applications and retrieve those members as needed.

The `SE_SHARED_SERVICES` object is a read-shared object and thus cannot be modified. The only time you can write to it is in the `sePrepareContextFunc` callback of the first context. Therefore, you want to ensure any initialization code that may write to this object, such as `seAddLibTable` calls, are put into the prepare context callback for your first context.

Take care when designing your applications and carefully consider the purpose of the data you are storing in the `SE_SERVICES` object. You may want that data to be per-context. In other cases, the data should be identical between contexts, and that is when you use the `SE_SHARED_SERVICES` object.

The `SE_SHARED_SERVICES` object is a synonym for `SE_SERVICES` if you do not have the read-only shared objects enabled. Thus, you can write your code to properly function when shared and use it unchanged in a non-shared build (determined by the options in your `jseopt.h` file) by using `SE_SHARED_SERVICES` when appropriate.

# ScriptEase JavaScript

ScriptEase is a scripting or programming language that allows a computer user or programmer to write simple scripts with tremendous power. The guiding principles for ScriptEase are **simplicity** and **power** which add up to easy elegance in scripting. Scripts are much easier to write and use than the source code for compiled languages such as C++.

ScriptEase uses JavaScript, one of the most popular scripting language in today's world, as its core language. In fact, ScriptEase uses the ECMAScript standard for JavaScript. ECMAScript is the core version of JavaScript which has been standardized by the European Computer Manufacturers Association and is the only standardization of JavaScript. ScriptEase closely follows and will follow this standardized JavaScript.

ScriptEase is not limited to JavaScript, as good as it may be. ScriptEase has enhanced the power of JavaScript by adding two objects, Clib and SELib, that have the power of the C programming language. Indeed, ScriptEase implements a scripting version of C which has the power of C in a simple scripting language. With the power of C readily available, computer users or programmers are able to accomplish any tasks that they pursue. Both JavaScript and C script can be intermingled in ScriptEase code, which allows scripters flexibility, power, and simplicity.

The following line is a complete script which could be saved as a script file and run as a program. The program simply displays a message, "A simple one line script," on a computer screen

```
Screen.writeln("A simple one line script")
```

The following code fragment uses a more structured approach to accomplish the same task. JavaScript and C share similar programming styles, such as the main() function shown in this fragment.

```
function main()
{
    Clib.puts("A simple one line script");
}
```

A ScriptEase script may be written using a very straightforward scripting approach as shown in the first example above, which is similar to the simple scripting of a DOS batch file. A second line could be added to the single line as shown in the following fragment.

```
Screen.writeln("A simple one line script")
Clib.puts("Now there are two lines")
```

The example using the main() function could be expanded as follows.

```
function main()
{
    Clib.puts("A simple one line script");
    Screen.writeln("Now there are two lines");
}
```

These examples illustrate how easily ScriptEase can be used in a simple scripting mode and how easily the power of functions can be put in a script, and not just the power of functions, but the power of C. They show how easily JavaScript and C script can be intermingled, since C is implemented as a JavaScript object. Functions and other programming concepts are explained in the following descriptions of the ScriptEase language. A tutorial section provides illustrations of scripts in addition to the example code fragments in the text.

Most JavaScript, other than ScriptEase, is part of web browsers and is used while users are connected to the Internet. Usually people are unaware that JavaScript is commonly being executed on their computers when they are connected to various Internet sites. Not only are they unaware, they are unable to write and execute scripts on their computers for their own uses. ScriptEase steps in at this point. ScriptEase Desktop is designed for users to control their own computers in a stand alone mode. Users do not have to be connected to the Internet to use ScriptEase, as they must be with other JavaScript interpreters.

Whether the desire is to write a simple script to copy a document to a backup folder or to write an entire data processing program, ScriptEase can do the job or any other job desired. ScriptEase has joined JavaScript and C. Further, ScriptEase adds commands and functions not available in standard implementations of either. In short, ScriptEase is the most powerful and advanced scripting language available today, and it achieves its power while still being simple to use.

The following sections of this manual will help you to start enjoying the power of ScriptEase.

---

## Basics of ScriptEase

### Case sensitivity

ScriptEase is case sensitive. A variable named "testvar" is a different variable than one named "TestVar", and both of them can exist in a script at the same time. Thus, the following code fragment defines two separate variables:

```
var testvar = 5
var TestVar = "five"
```

All identifiers in ScriptEase are case sensitive. For example, to display the word "dog" on the screen, the `Screen.write()` method could be used: `Screen.write("dog")`. But, if the capitalization is changed to something like, `Screen.Write("dog")`, then the ScriptEase interpreter generates an error message. Control statements and preprocessor directives are also case sensitive. For example, the statement `while` is valid, but the word `While` is not. The directive `#if` works, but the letters `#IF` fail.

### White space characters

White space characters, space, tab, carriage-return and new-line, govern the spacing and placement of text. White space makes code more readable for humans, but is ignored by the interpreter.

Lines of script end with a carriage-return, and each line is usually a separate statement. (Technically, in many editors, lines end with a carriage-return and

linefeed pair, "\r\n".) Since the interpreter usually sees one or more white space characters between identifiers as simply white space, the following ScriptEase statements are equivalent to each other:

```
var x=a+b
var x = a + b
var x =      a      +      b
var x = a
      + b
```

White space separates identifiers into separate entities. For example, "ab" is one variable name, and "a b" is two. Thus, the fragment, `var ab = 2` is valid, but `var a b = 2` is not.

Many programmers use all spaces and no tabs, because tab size settings vary from editor to editor and programmer to programmer. By using spaces only, the format of a script will look the same on all editors. All scripts provided by Nombas with ScriptEase use spaces only.

## Comments

A comment is text in a script to be read by humans and not the interpreter which skips over comments. Comments help people to understand the purpose and program flow of a program. Good comments, which explain lines of code well, help people alter code that they have written in the past or that was written by others.

There are two formats for comments: single-line comments (end of line comments) and multi-line comments (block comments). Single-line comments may contain any character except a line terminator character ("\n").

- Single-line comments begin with two slash characters, "//". Any text after two consecutive slash characters is ignored to the end of the current line. The interpreter begins interpreting text as code on the next line.
- Multi-line comments are enclosed within a beginning block comment, "/\*", and an end of block comment, "\*/". Any text between these markers is a comment, even if the comment extends over multiple lines. Multi-line comments may not be nested within other multi-line comments, but single-line comments can exist within multi-line comments.

The following code fragments are examples of valid comments:

```
// this is a single-line comment

/* this is a multi-line comment
   This is one big comment block.
   // this comment is okay inside the block
   Isn't it pretty?
*/

var FavoriteAnimal = "dog"; // except for poodles

//This line is a comment but
var TestStr = "this line is not a comment";
```

## Expressions, statements, and blocks

An expression or statement is any sequence of code that performs a computation or an action, such as the code `var TestSum = 4 + 3` which computes a sum and assigns it to a variable. ScriptEase code is executed one statement at a time in the order in which it is read. Many programmers put semicolons at the end of statements, although they are not required. Each statement is usually written on a separate line, with or without semicolons, to make scripts easier to read and edit.

A statement block is a group of statements enclosed in curly braces, "`{}`", which indicate that the enclosed individual statements are a group and are to be treated as one statement. A block can be used anywhere that a single statement can.

A while statement causes the statement after it to be executed in a loop. By enclosing multiple statements in curly braces, they are treated as one statement and are executed in the while loop. The following fragment illustrates:

```
while( ThereAreUncalledNamesOnTheList() == true)
{
    var name = GetNameFromTheList();
    CallthePerson(name);
    LeaveTheMessage();
}
```

All three lines after the while statement are treated as a unit. If the braces were omitted, the while loop would only apply to the first line. With the braces, the script goes through all lines until everyone on the list has been called. Without the braces, the script goes through all names on the list, but only the last one is called. Two very different procedures.

Statements within blocks are often indented for easier reading.

---

## Identifiers

Identifiers are merely names for variables and functions. Programmers must know the names of built in variables and functions to use them in scripts and must know some rules about identifiers to define their own variables and functions. The following rules are simple and intuitive.

- Identifiers may use only ASCII letters, upper or lower case, digits, the underscore, "`_`", and the dollar sign, "\$". That is, they may use only characters from the following sets of characters.  
"abcdefghijklmnopqrstuvwxyz"  
"ABCDEFGHIJKLMNOPQRSTUVWXYZ"  
"0123456789"  
"\_\$"
- Identifiers may **not** use the following characters.  
"+- <>|=!\*/%^~?:{ }; () [ ] . ' ` # , "
- Identifiers must begin with a letter, underscore, or dollar sign, but may have digits anywhere else.
- Identifiers may not have white space in them since white space separates identifiers for the interpreter.
- Identifiers may be as long a programmer needs.

The following identifiers, variables and functions, are valid:

```
Sid
```

```

Nancy7436
annualReport
sid_and_nancy_prepared_the_annualReport
$alice
CalculateTotal()
$SubtractLess()
_Divide$All()

```

The following identifiers, variables and functions, are not valid:

```

1sid
2nancy
this&that
Sid and Nancy
ratsAndCats?
=Total()
(Minus)()
Add Both Figures()

```

## Prohibited identifiers

The following words or tokens have special meaning for the interpreter and should not or may not be used as identifiers, neither as variable nor as function names. See [identifiers to avoid](#) for a list of words to shun as identifiers.

abstract	as	break	boolean	byte	case
catch	char	class	const	continue	debugger
default	delete	do	double	else	enum
export	extends	false	final	finally	float
for	function	goto	if	implements	import
in	instanceof	int	interface	is	long
namespace	native	new	null	package	private
protected	public	return	short	static	super
switch	synchronized	this	throw	throws	transient
true	try	typeof	use	var	void
volatile	while	with			

## Identifiers to avoid

Safe programming suggests that the following words or tokens should not be used as identifiers, neither as variable nor as function names. See [prohibited identifiers](#) for a list of words to that simply should not be used as identifiers.

arguments	Array	Boolean	Date
decodeURI	decodeURIComponent	encodeURIComponent	
Error	escape	eval	EvalError
Function	Infinity	isFinite	isNaN
Math	NaN	Number	Object
parseFloat	parseInt	RangeError	ReferenceError
RegExp	String	SyntaxError	TypeError
undefined	unescape	URIError	

## Variables

A variable is an identifier to which data may be assigned. Variables are used to store and represent information in a script. Variables may change their values, but literals may not. For example, if programmers want to display a name literally, they must use something like the following fragment multiple times.

```
Screen.writeln("Rumpelstiltskin Henry Constantinople")
```

But they could use a variable to make their task easier, as in the following.

```
var Name = "Rumpelstiltskin Henry Constantinople"
Screen.write(Name)
```

Then they can use shorter lines of code for display and use the same lines of code repeatedly by simply changing the contents of the variable Name.

## Variable scope

Variables in ScriptEase may be either global or local. Global variables may be accessed and modified from anywhere in a script. Local variables may only be accessed from the functions in which they are created. There are no absolute rules for preferring or using global or local variables. Each type has value. In general, programmers prefer to use local variables when reasonable since they facilitate modular code that is easier to alter and develop over time. It is generally easier to understand how local variables are used in a single function than how global variables are used throughout an entire program. Further, local variables conserve system resources.

To make a local variable, declare it in a function using the var keyword:

```
var perfectNumber;
```

A value may be assigned to a variable when it is declared:

```
var perfectNumber = 28;
```

The default behavior of ScriptEase is that variables declared outside of any function or inside a function without the var keyword are global variables. However, this behavior can be changed by the `DefaultLocalVars` and `RequireVarKeyword` settings of the `#option` preprocessor directive. This directive is explained in the section on preprocessing. For now, consider the following code fragment.

```
var a = 1;
function main()
{
    b = 1;
    var d = 3;
    someFunction(d);
}

function someFunction(e)
{
    var c = 2
    ...
}
```

In this example, a and b are both global variables, since a is declared outside of a function and b is defined without the var keyword. The variables, d and c, are both local, since they are defined within functions with the var keyword. The

variable `c` may not be used in the `main()` function, since it is `undefined` in the scope of that function. The variable `d` may be used in the `main()` function and is explicitly passed as an argument to `someFunction()` as the parameter `e`. The following lines show which variables are available to the two functions:

```
main():          a, b, d
someFunction(): a, b, c, e
```

It is possible, though not usually a good idea, to have local and global variables with the same name. In such a case, a global variable must be referenced as a property of the global object, and the variable name used by itself refers to the local variable. In the fragment above, the global variable `a` can be referenced anywhere in its script by using: `global.a`.

## Function identifier

Functions are identified by names, as variables are. Functions perform script operations, and variables store data. Functions do the work of a script and will be discussed in more detail later. The reason they are mentioned here is simply to point out that they have identifiers, names, that follow the same rules for identifiers as variable names do.

## Function scope

Functions are all global in scope, much like global variables. A function may not be declared within another function so that its scope is merely within a certain function or section of a script. All functions may be called from anywhere in a script. If it is helpful, think of functions as methods of the global object. The following two code fragments do exactly the same thing. The first calls a function, `SumTwo()`, as a function, and the second calls `SumTwo()` as a method of the global object.

```
// fragment one
function SumTwo(a, b)
{
    return a + b
}

Screen.writeln(SumTwo(3, 4))

// fragment two
function SumTwo(a, b)
{
    return a + b
}

Screen.writeln(global.SumTwo(3, 4))
```

---

## Data types

Data types in ScriptEase can be classified into three groupings: primitive, composite, and special. In a script, data can be represented by literals or variables. The following lines illustrates variables and literals:

```
var TestVar = 14;
var aString = "test string";
```

The variable TestVar is assigned the literal 14, and the variable aString is assigned the literal "test string". After these assignments of literal values to variables, the variables can be used anywhere in a script where the literal values could to be used.

In the fragment above which defines and uses the function SumTwo(), the literals, 3 and 4, are passed as arguments to the function SumTwo() which has corresponding parameters, a and b. The parameters, a and b, are variables for the function the hold the literal values that were passed to it.

Data types need to be understood in terms of their literal representations in a script and of their characteristics as variables.

Data , in literal or variable form, is assigned to a variable with an assignment operator which is often merely an equal sign, "=" as the following lines illustrate.

```
var happyVariable = 7;
var joyfulVariable = "free chocolate";
var theWorldIsFlat = true;
var happyToo = happyVariable;
```

The first time a variable is used, its type is determined by the interpreter, and the type remains until a later assignment changes the type automatically. The example above creates three variables, each of a different type. The first is a number, the second is a string, and the third is a boolean variable. Variable types are described below. Since ScriptEase automatically converts variables from one type to another when needed, programmers normally do not have to worry about type conversions as they do in strongly typed languages, such as C.

## Primitive data types

Variables that have primitive data types pass their data by value, by actually copying the data to the new location. The following fragment illustrates:

```
var a = "abc";
var b = ReturnValue(a);

function ReturnValue(c)
{
    return c;
}
```

After "abc" is assigned to variable a, two copies of the string "abc" exist, the original literal and the copy in the variable a. While the function ReturnValue is active, the parameter/variable c has a copy, and three copies of the string "abc" exist. If c were to be changed in such a function, variable a, which was passed as an argument to the function, would remain unchanged. After the function ReturnValue is finished, a copy of "abc" is in the variable b, but the copy in the variable c in the function is gone because the function is finished. During the execution of the fragment, as many as three copies of "abc" exist at one time.

The primitive data types are: Number, Boolean, and String.

### Number type

#### Integer

Integers are whole numbers. Decimal integers, such as 1 or 10, are the most common numbers encountered in daily life. ScriptEase has three notations for integers: decimal, hexadecimal, and octal.

### **Decimal**

Decimal notation is the way people write numbers in everyday life and uses base 10 digits from the set of 0-9. Examples are:

```
1, 10, 0, and 999  
var a = 101;
```

### **Hexadecimal**

Hexadecimal notation uses base 16 digits from the sets of 0-9, A-F, and a-f. These digits are preceded by 0x. ScriptEase is not case sensitive when it comes to hexadecimal numbers. Examples are:

```
0x1, 0x01, 0x100, 0x1F, 0x1f, 0xABCD  
var a = 0x1b2E;
```

### **Octal**

Octal notation uses base 8 digits from the set of 0-7. These digits are preceded by 0. Examples are:

```
00, 05, and 077  
var a = 0143;
```

### **Floating point**

Floating point numbers are number with fractional parts which are often indicated by a period, for example, 10.33. Floating point numbers are often referred to as floats.

### **Decimal floats**

Decimal floats use the same digits as decimal integers but allow a period to indicate a fractional part. Examples are:

```
0.32, 1.44, and 99.44  
var a = 100.55 + .45;
```

### **Scientific floats**

Scientific floats are often used in the scientific community for very large or small numbers. They use the same digits as decimals plus exponential notation. Scientific notation is sometimes referred to as exponential notation. Examples are:

```
4.087e2, 4.087E2, 4.087e+2, and 4.087E-2  
var a = 5.321e33 + 9.333e-2;
```

### **Boolean type**

Booleans may have only one of two possible values: `false` or `true`. Since ScriptEase automatically converts values when appropriate, Booleans can be used as they are in languages such as C. Namely, `false` is zero, and `true` is non-zero. A script is more precise when it uses the actual ScriptEase values, `false` and `true`, but it will work using the concepts of zero and not zero. When

a Boolean is used in a numeric context, it is converted to 0, if it is `false`, and 1, if it is `true`.

## String type

A String is a series of characters linked together. A string is written using quotation marks, for example: "I am a string", 'so am I', `me too`, and "344". The string "344" is different from the number 344. The first is an array of characters, and the second is a value that may be used in numerical calculations.

ScriptEase automatically converts strings to numbers and numbers to string, depending on context. If a number is used in a string context, it is converted to a string. If a string is used in a number context, it is converted to a numeric value. Automatic type conversion is discussed more fully in a later section

Strings, though classified as a primitive, are actually a hybrid type that shares characteristics of primitive and composite data types. Strings are discussed more fully a later section.

## Composite data types

Whereas primitive types are passed by value, composite types are passed by reference. When a composite type is assigned to a variable or passed to a parameter, only a reference that points to its data is passed. The following fragment illustrates:

```
var AnObj = new Object;
AnObj.name = "Joe";
AnObj.old = ReturnName(AnObj)

function ReturnName(CurObj)
{
    return CurObj.name
}
```

After the object `AnObj` is created, the string "Joe" is assigned, by value since a property is a variable within an Object, to the property `AnObj.name`. Two copies of the string "Joe" exist. When `AnObj` is passed to the function `ReturnName`, it is passed by reference. `CurObj` does not receive a copy of the Object, but only a reference to the Object. With this reference, `CurObj` can access every property and method of the original. If `CurObj.name` were to be changed while the function was executing, then `AnObj.name` would be changed at the same time. When `AnObj.old` receives the return from the function, the return is assigned by value, and a copy of the string "Joe" transferred to the property. Thus, `AnObj` holds two copies of the string "Joe": one in the property `.name` and one in the property `.old`. Three total copies of "Joe" exist, counting the original string literal.

The composite data types are: Object and Array.

## Object type

An object is a compound data type, consisting of one or more pieces of data of any type which are grouped together in an object. Data that are part of an object are called properties of the object. The Object data type is similar to the structure data type in C and in previous versions of ScriptEase. The object data type also allows functions, called methods, to be used as object properties. Indeed, in ScriptEase, functions are considered to be like variables. But for practical

programming, think of objects as having methods, which are functions, and properties, which are variables and constants.

Objects and their characteristics are discussed more fully in a later section.

## Array type

An array is a series of data stored in a variable that is accessed using index numbers that indicate particular data. The following fragments illustrate the storage of the data in separate variables or in one array variable:

```
var Test0 = "one";
var Test1 = "two";
var Test2 = "three";

var Test = new Array;
Test[0] = "one";
Test[1] = "two";
Test[2] = "three";
```

After either fragment is executed, the three strings are stored for later use. In the first fragment, three separate variables have the three separate strings. These variables must be used separately. In the second fragment, one variable holds all three strings. This array variable can be used as one unit, and the strings can be accessed individually. The similarities, in grouping, between Arrays and Objects is more than slight. In fact, Arrays and Objects are both objects in ScriptEase with different notations for accessing properties. For practical programming, Arrays may be considered as a data type of their own.

Arrays and their characteristics are discussed more fully in a later section.

## Special values

### undefined

If a variable is created or accessed with nothing assigned to it, it is of type `undefined`. An `undefined` variable merely occupies space until a value is assigned to it. When a variable is assigned a value, it is assigned a type according to the value assigned. Though variables may be of type `undefined`, there is no literal representation for `undefined`. Consider the following invalid fragment.

```
var test;
if (test == undefined)
    Screen.writeln("test is undefined")
```

After `var test` is declared, it is `undefined` since no value has been assigned to it. But, the `test, test == undefined`, is invalid because there is no way to literally represent `undefined`.

### null

The value `null` is a special data type that indicates that a variable is empty, a condition that is different from being `undefined`. A `null` variable holds no value, though it might have previously. The `null` type is represented literally by the identifier, `null`. Since ScriptEase automatically converts data types, `null` is both useful and versatile. The code fragment above will work if `undefined` is changed to `null`, as shown in the following:

```
var test;
if (test == null)
```

```
Screen.write("test is undefined")
```

Since `null` has a literal representation, assignments like the following are valid:

```
var test = null;
```

Any variable that has been assigned a value of `null` can be compared to the `null` literal.

The value `null` is an internal standard ECMAScript value. However, the value `NULL` is defined as `0` in *seutil.jsh* and is used in some scripts as it is found in C based documentation. Because of automatic conversion in JavaScript, the two values often operate alike, but not always. They are two separate values.

## NaN

The `NaN` type means "Not a Number". `NaN` is an acronym for the phrase. However, `NaN` does not have a literal representation. To test for `NaN`, the function, `global.isNaN()`, must be used, as illustrated in the following fragment:

```
var Test = "a string";
if (isNaN(parseInt(Test)))
    Screen.writeln("Test is Not a Number");
```

When the `global.parseInt()` function tries to parse the string "a string" into an integer, it returns `NaN`, since "a string" does not represent a number like the string "22" does.

## Number constants

Several numeric constants can be accessed as properties of the `Number` object, though they do not have a literal representation.

Constant	Value	Description
<code>Number.MAX_VALUE</code>	1.7976931348623157e+308	Largest number (positive)
<code>Number.MIN_VALUE</code>	2.2250738585072014e- 308	Smallest number (negative)
<code>Number.NaN</code>	<code>NaN</code>	Not a Number
<code>Number.POSITIVE_INFINITY</code>	Infinity	Number above <code>MAX_VALUE</code>
<code>Number.NEGATIVE_INFINITY</code>	- Infinity	Number below <code>MIN_VALUE</code>

---

## Automatic type conversion

When a variable is used in a context where it makes sense to convert it to a different type, `ScriptEase` automatically converts the variable to the appropriate type. Such conversions most commonly happen with numbers and strings. For example:

```
"dog" + "house" == "doghouse" // two strings are joined
"dog" + 4 == "dog4"           // a number is converted
4 + "4" == "44"               // to a string
4 + 4 == 8                     // two numbers are added
23 - "17" == 6                 // a string is converted
                                // to a number
```

Converting numbers to strings is fairly straightforward. However, when converting strings to numbers there are several limitations. While subtracting a string from a number or a number from a string converts the string to a number and subtracts the two, adding the two converts the number to a string and concatenates them. String always convert to a base 10 number and must not contain any characters other than digits. The string "110n" will not convert to a number, because the ScriptEase interpreter does not know what to make of the "n" character.

You can specify more stringent conversions by using the global methods, `global.parseInt()` and `global.parseFloat()` methods. Further, ScriptEase has many global functions to cast data as a specific type, functions that are not part of the ECMAScript standard. These functions are described in the section on global functions that are specific to ScriptEase.

---

## Properties and methods of basic data types

The basic data types, such as Number and String, have properties and methods assigned to them that may be used with any variable of that type. For example, all String variables may use all String methods.

The properties and methods of the basic data types are retrieved in the same way as from objects. For the most part, they are used internally by the interpreter, but you may use them if choose. For example, if you have a numeric variable called number and you want to convert it to a string, you can use the `toString()` method as illustrated in the following fragment.

```
var n = 5
var s = n.toString()
```

After this fragment executes, the variable n contains the number 5 and the variable s contains the string "5".

The following two methods are common to all variables and data types.

### **toString()**

This method returns the value of a variable expressed as a string. Every data type has `toString()` as a method. Thus, `toString()` is documented here and not in every conceivable place that it might be used.

### **valueOf()**

This method returns the value of a variable. Every data type has `valueOf()` as a method. Thus, `valueOf()` is documented here and not in every conceivable place that it might be used.

---

## Operators

### Object operator

The object operator is a period, ".". This operator allows properties and methods of an object to be accessed and used. For example, `Math.abs()` is a method of the **Math object**. It may be accessed as follows:

```
var AbsNum = Math.abs(-3)
```

The variable `AbsNum` now equals 3. The variable `AbsNum` is an instance of the `Number` object, not an instance of the `Math` object. Why? It is assigned the number 3 which is the return of the `Math.abs()` method.

The `Math.abs()` method is a static method, that is, it is used directly with the `Math` object instead of an instance of the object. Many methods are instance methods, that is, they are used with instances of an object instead of the object itself. The `String.substring()` method is an instance method of the **String object**. An instance method is not used with an object itself but only with instances of an object. The `String.substring()` method is never used with the `String` object as `String.substring()`. The following fragment declares and initializes a string variable, which is an instance of the `String` object, and then uses the `String.substring()` method with this instance by using the object operator.

```
var s = "One Two Three";  
var new = s.substring(4,7);
```

The variable `s` is an instance of the `String` object since it is initialized as a string. The variable `new` now equals "Two" and is also an instance of the `String` object since the `String.substring()` method returns a string.

The main point here is that the period "." is an object operator that may be used with both static and instance methods and properties. A method or property is simply attached to an appropriate identifier using the object operator, which then accesses the method or property.

## Mathematical operators

Mathematical operators are used to make calculations using mathematical data. The following sections illustrate the mathematical operators in ScriptEase.

### Basic arithmetic

The arithmetic operators in ScriptEase are pretty standard.

=	assignment	assigns a value to a variable
+	addition	adds two numbers
-	subtraction	subtracts a number from another
*	multiplication	multiplies two numbers
/	division	divides a number by another
%	modulo	returns a remainder after division

The following are examples using variables and arithmetic operators.

```
var i;  
i = 2;           i is now 2  
i = i + 3;      i is now 5, (2+3)  
i = i - 3;      i is now 2, (5-3)  
i = i * 5;      i is now 10, (2*5)  
i = i / 3;      i is now 3, (10/3) (remainder is ignored)  
i = 10;         i is now 10
```

```
i = i % 3;           i is now 1, (10%3)
```

Expressions may be grouped to affect the sequence of processing. All multiplications and divisions are calculated for an expression before additions and subtractions unless parentheses are used to override the normal order. Expressions inside parentheses are processed first, before other calculations. In the following examples, the information inside square brackets, "[ ]," are summaries of calculations provided with these examples and not part of the calculations.

Notice that:

```
4 * 7 - 5 * 3;      [28 - 15 = 13]
```

has the same meaning, due to the order of precedence, as:

```
(4 * 7) - (5 * 3); [28 - 15 = 13]
```

but has a different meaning than:

```
4 * (7 - 5) * 3;   [4 * 2 * 3 = 24]
```

which is still different from:

```
4 * (7 - (5 * 3)); [4 * (-8) = - 32]
```

The use of parentheses is recommended in all cases where there may be confusion about how the expression is to be evaluated, even when they are not necessary.

### Assignment arithmetic

Each of the above operators can be combined with the assignment operator, =, as a shortcut for performing operations. Such assignments use the value to the right of the assignment operator to perform an operation with the value to the left. The result of the operation is then assigned to the value on the left.

=	assignment	assigns a value to a variable
+=	assign addition	adds a value to a variable
-=	assign subtraction	subtracts a value from a variable
*=	assign multiplication	multiplies a variable by a value
/=	assign division	divides a variable by a value
%=	assign remainder	returns a remainder after division

The following lines are examples using assignment arithmetic.

```
var i;  
i = 2;           i is now 2  
i += 3;         i is now 5, (2+3)      same as i = i + 3  
i -= 3;         i is now 2, (5-3)      same as i = i - 3  
i *= 5;         i is now 10, (2*5)     same as i = i * 5  
i /= 3;         i is now 3, (10/3)     same as i = i / 3  
i = 10;        i is now 10  
i %= 3;        i is now 1, (10%3)     same as i = i % 3
```

### Auto-increment (++) and auto-decrement (--)

To add or subtract one, 1, to or from a variable, use the auto-increment, ++, or auto-decrement, --, operator. These operators add or subtract 1 from the value to which they are applied. Thus, i++ is a shortcut for i += 1, which is a shortcut for i = i + 1.

These operators can be used before, as a prefix operator, or after, as a postfix operator, their variables. If they are used before a variable, it is altered before it is used in a statement, and if used after, the variable is altered after it is used in the statement. The following lines demonstrates prefix and postfix operations.

```

i = 4;          i is 4
j = ++i;       j is 5, i is 5      (i was incremented before use)
j = i++;       j is 5, i is 6      (i was incremented after use)
j = --i;       j is 5, i is 5      (i was decremented before use)
j = i--;       j is 5, i is 4      (i was decremented after use)
i++;          i is 5                (i was incremented)

```

## Bit operators

ScriptEase contains many operators for operating directly on the bits in a byte or an integer. Bit operations require a knowledge of bits, bytes, integers, binary numbers, and hexadecimal numbers. Not every programmer needs to or will choose to use bit operators.

<<	shift left	i = i << 2;
<<=	assignment shift left	i <<= 2;
>>	shift right	i = i >> 2;
>>=	assignment shift right	i >>= 2;
>>>	shift left with zeros	i = i >>> 2
>>>=	assignment shift left with zeros	i >>>= 2
&	bitwise and	i = i & 1
&=	assignment bitwise and	i &= 1;
	bitwise or	i = i   1
=	assignment bitwise or	i  = 1;
^	bitwise xor, exclusive or	i = i ^ 1
^=	assignment bitwise xor, exclusive or	i ^= 1
~	Bitwise not, complement	i = ~i;

## Logical operators and conditional expressions

Logical operators compare two values and evaluate whether the resulting expression is `false` or `true`. The value `false` is zero, and `true` is not `false`, that is, anything not zero. A variable or any other expression may be `false` or `true`, that is, zero or non-zero. An expression that does a comparison is called a conditional expression.

Many values are evaluated as `true`, in fact, everything except 0. It is often safer to make comparisons based on `false`, which is only one value, rather than to `true`, which can be many. Expressions can be combined with logic operators to make complex `true/false` decisions.

Logical operators are used to make decisions about which statements in a script will be executed, based on how a conditional expression evaluates. As an

example, suppose that you are designing a simple guessing game. The computer thinks of a number between 1 and 100, and you guess what it is. The computer tells you if you are right or not and whether your guess is higher or lower than the target number. This procedure uses the if statement, which is introduced in the next section. Basically, if the conditional expression in the parenthesis following an if statement is `true`, the statement block following the if statement is executed. If `false`, the statement block is ignored, and the computer continues executing the script at the next statement after the ignored block. The script might have a structure similar to the one below in which `GetTheGuess()` is a function that gets your guess.

```
var guess = GetTheGuess(); //get the user input
if (guess > target_number)
{
    ...guess is too high...
}

if (guess < target_number)
{
    ...guess is too low...
}

if (guess == target_number)
{
    ...you guessed the number!...
}
```

This example is simple, but it illustrates how logical operators can be used to make decisions in ScriptEase.

The logical operators are:

!	not	reverses an expression. If (a+b) is <code>true</code> , then <code>!(a+b)</code> is <code>false</code> .
&&	and	true if, and only if, both expressions are <code>true</code> . Since both expressions must be <code>true</code> for the statement as a whole to be <code>true</code> , if the first expression is <code>false</code> , there is no need to evaluate the second expression, since the whole expression is <code>false</code> .
	or	true if either expression is <code>true</code> . Since only one of the expressions in the or statement needs to be <code>true</code> for the expression to evaluate as <code>true</code> , if the first expression evaluates as <code>true</code> , the interpreter returns <code>true</code> and does not bother with evaluating the second.
==	equality	true if the values are equal, else <code>false</code> . Do not confuse the equality operator, <code>==</code> , with the assignment operator, <code>=</code> .
!=	inequality	true if the values are not equal, else <code>false</code> .
===	identity	true if the values are identical or strictly equal, else <code>false</code> . No type conversions are performed as with the equality operator.

<code>!==</code>	non-identity	<code>true</code> if the values are not identical or not strictly equal, else <code>false</code> . No type conversions are performed as with the inequality operator.
<code>&lt;</code>	less than	<code>a &lt; b</code> is <code>true</code> if <code>a</code> is less than <code>b</code> .
<code>&gt;</code>	greater than	<code>a &gt; b</code> is <code>true</code> if <code>a</code> is greater than <code>b</code> .
<code>&lt;=</code>	less than or equal to	<code>a &lt;= b</code> is <code>true</code> if <code>a</code> is less than or equal to <code>b</code> .
<code>&gt;=</code>	greater than or equal to	<code>a &gt;= b</code> is <code>true</code> if <code>a</code> is greater than <code>b</code> .

Remember, the assignment operator, `=`, is different than the equality operator, `==`. If you use one equal sign when you intend two, your script will not function the way you want it to. This is a common pitfall, even among experienced programmers. The two meanings of equal signs must be kept separate, since there are times when you have to use them both in the same statement, and there is no way the computer can differentiate them by context.

## Concatenation operator

The plus `+` may also be used to concatenate strings. The following expression:

```
"one" + "--" + "two"
```

results in the following string:

```
"one--two"
```

## delete operator

The `delete` operator deletes properties from objects and elements from arrays. Deleted properties and arrays are actually undefined. Any memory cleanup is handled by normal garbage collection.

The following fragment defines an array with three elements: 0, 1, and 2, and an object with three properties: four, five, and six. It then deletes the middle, that is, the second, element of the array and property of the object.

```
var a = ["one", "two", "three"];
var o = {four:444, five:555, six:666};

delete(a[1]);
delete(o.five);
```

There are several ways to eliminate the data in a property of an object or in an element of an array. The `delete` operator is the most complete way. Three other techniques use `undefine()`, `undefined`, and `void`, as illustrated next:

```
undefine(a[1]);
undefine(o.five);

a[1] = undefined;
o.five = undefined;

a[1] = void a[1];
o.five = void o.five;
```

These three techniques may be used with any variable, whereas the `delete` operator may be used only with properties of objects and elements of arrays.

Generally, `delete` is the best to use with properties of objects and elements of arrays, though in specific situations the other techniques might be preferable.

See [global.undefine\(\)](#) and [undefined](#) for more information.

## in operator

The `in` operator determines if a property exists in an object. The following script fragment illustrates for the discussion in this section:

```
var isProp;
var obj = {one:111, two:222, Three:333};
var test = 'one';

isProp = test in obj;

if (isProp)
    Screen.writeln(isProp);
Screen.writeln('two' in obj);
Screen.writeln('three' in obj);

/*****
Display is:
    true
    true
    false
*****/
```

The script above defines an object, `obj`, with three properties: "one", "two", and "Three" (note the capitalization). The `in` operator is used three times to see if the following strings are properties in `obj`: "one", "two", "three" (note the capitalization). The first two uses of `in` result in `true` and the third in `false`. Look at the expression "`test in obj`". The expression to the left, in this case `test`, of the `in` operator must be a string or be able to convert to a string (since properties of objects are represented as strings). The expression to the right must be an object or array.

ScriptEase JavaScript has a [global.defined\(\)](#) function which is useful. The `in` operator may be used in a similar way. In the following fragment, both `in` and `defined()` result in `true`, and the display is:

```
true
true
```

The fragment is:

```
var test = 'TEST';

Screen.writeln('test' in global);
Screen.writeln(defined(test));
```

## instanceof operator

The `instanceof` operator, which also may be used as `instanceof()`, determines if a variable is an instance of a particular object. Since the variable `s` is created as an instance of the `String` object in the following code fragment, the second line displays `true`.

```
var s = new String("abcde");
```

```
Screen.writeln(s instanceof String);
```

The display is:

```
true
```

The second line could also be written as:

```
Screen.writeln(s instanceof (String));
```

The `instanceof` operator does not work with the class of an object, rather it determines if a variable was constructed from an object. In the example above, the variable `s` was defined as an instance of `String` so it is an instance of the `String` object and is in the class of `String`. That is, both of the following lines display `true`:

```
Screen.writeln(s instanceof (String));  
Screen.writeln(s._class == "String");
```

The display is:

```
true  
true
```

The following code defines a new object and defines the variable `ms` as an instance of `MyString`, a user defined object. In this case, the variable `ms` is an instance of `MyString` but is in the class of `Object`.

```
var ms = new MyString("abcde");  
Screen.writeln(ms instanceof MyString);  
Screen.writeln(ms._class == "Object");  
ms.show();
```

```
function MyString(string)  
{  
  
    this.data = string;  
    return this;  
} // MyString  
  
function MyString.prototype.show()  
{  
    Screen.writeln(this.data);  
} // MyString.prototype.show
```

The display is:

```
true  
true  
abcde
```

## typeof operator

The `typeof` operator, which also may be used as `typeof()`, provides a way to determine and to test the data type of a variable and may use either of the following notations, with or without parentheses.

```
var result = typeof variable  
var result = typeof(variable)
```

After either line, the variable `result` is set to a string that represents the variable's type: "undefined", "boolean", "string", "object", "number", or "function".

---

## Flow decisions statements

This section describes statements that control the flow of a program. Use these statements to make decisions and to repeatedly execute statement blocks.

### if

The `if` statement is the most commonly used mechanism for making decisions in a program. It allows you to test a condition and act on it. If an `if` statement finds the condition you test to be `true`, the statement or statement block following it are executed. The following fragment is an example of an `if` statement.

```
if ( goo < 10 )
{
    Screen.write("goo is smaller than 10\n");
}
```

### else

The `else` statement is an extension of the `if` statement. It allows you to tell your program to do something else if the condition in the `if` statement was found to be `false`. In ScriptEase code, it looks like the following.

```
if ( goo < 10 )
{
    Screen.write("goo is smaller than 10\n");
}
else
{
    Screen.write("goo is not smaller than 10\n");
}
```

To make more complex decisions, `else` can be combined with `if` to match one out of a number of possible conditions. The following fragment illustrates using `else` with `if`.

```
if ( goo < 10 )
{
    Screen.write("goo is less than 10\n");
    if ( goo < 0 )
    {
        Screen.write("goo is negative; so it's less than 10\n");
    }
}
else if ( goo > 10 )
{
    Screen.write("goo is greater than 10\n");
}
else
{
    Screen.write("goo is 10\n");
}
```

### while

The `while` statement is used to execute a particular section of code, over and over again, until an expression evaluates as `false`.

```
while (expression)
{
    DoSomething();
}
```

When the interpreter comes across a `while` statement, it first tests to see whether the expression is `true` or not. If the expression is `true`, the interpreter carries out the statement or statement block following it. Then the interpreter tests the expression again. A while loop repeats until the test expression evaluates to `false`, whereupon the program continues after the code associated with the `while` statement.

The following fragment illustrates a `while` statement with a two lines of code in a statement block.

```
while( ThereAreUncalledNamesOnTheList() != false)
{
    var name=GetNameFromTheList();
    SendEmail(name);
}
```

## do {...} while

The `do` statement is different from the `while` statement in that the code block is executed at least once, before the test condition is checked.

```
var value = 0;
do
{
    value++;
    ProcessData(value);
} while( value < 100 );
```

The code used to demonstrate the `while` statement could also be written as the following fragment.

```
do
{
    var name = GetNameFromTheList();
    SendEmail(name)
} while (name != TheLastNameOnTheList());
```

Of course, if there are no names on the list, the script will run into problems!

## for

The `for` statement is a special looping statement. It allows for more precise control of the number of times a section of code is executed. The `for` statement has the following form.

```
for ( initialization; conditional; loop_expression )
{
    statement
}
```

The initialization is performed first, and then the expression is evaluated. If the result is `true` or if there is no conditional expression, the statement is executed.

Then the `loop_expression` is executed, and the expression is re-evaluated, beginning the loop again. If the expression evaluates as `false`, then the statement is not executed, and the program continues with the next line of code after the statement. For example, the following code displays the numbers from 1 to 10.

```
for(var x=1; x<11; x++)
{
    Screen.write(x);
}
```

None of the statements that appear in the parentheses following the `for` statement are mandatory, so the above code demonstrating the `while` statement would be rewritten this way if you preferred to use a `for` statement:

```
for( ; ThereAreUncalledNamesOnTheList() ; )
{
    var name=GetNameFromTheList();
    SendEmail(name)
}
```

Since we are not keeping track of the number of iterations in the loop, there is no need to have an initialization or `loop_expression` statement. You can use an empty `for` statement to create an endless loop:

```
for(;;)
{
    //the code in this block will repeat forever,
    //unless the program breaks out of the for loop somehow.
}
```

## break

`Break` and `continue` are used to control the behavior of the looping statements: `for`, `switch`, `while`, and `do ... while`. The `break` statement terminates the innermost loop of `for`, `while`, or `do` statements. The program resumes execution on the next line following the loop. The following code fragment does nothing but illustrate the `break` statement.

```
for(;;)
{
    break;
}
```

The `break` statement is also used at the close of a `case` statement, as shown below. See `switch, case, and default`.

## continue

The `continue` statement ends the current iteration of a loop and begins the next. Any conditional expressions are reevaluated before the loop reiterates. The `continue` statement works with the same loops as the `break` statement.

## switch, case, and default

The `switch` statement makes a decision based on the value of a variable or statement. The `switch` statement follows the following format:

```
switch( switch_variable )
```

```

{
  case value1:
    statement1
    break;
  case value2:
    statement2
    break;

  ...

  default:
    default_statement
}

```

The variable `switch_variable` is evaluated, and then it is compared to all of the values in the case statements (`value1`, `value2`, . . . , `default`) until a match is found. The statement or statements following the matched case are executed until the end of the `switch` block is reached or until a `break` statement exits the `switch` block. If no match is found, the `default` statement is executed, if there is one.

For example, suppose you had a series of account numbers, each beginning with a letter that determines what type of account it is. You could use a `switch` statement to carry out actions depending on that first letter. The same task could be accomplished with a series of nested `if` statements, but they require much more typing and are harder to read.

```

switch ( key[0] )
{
  case 'A':
    Screen.write("A"); //handle 'A' accounts...
    break;
  case 'B':
    Screen.write("B"); //handle 'B' accounts...
    break;
  case 'C':
    Screen.write("C"); //handle 'C' accounts...
    break;
  default:
    Screen.write("Invalid account number.\n");
    break;
}

```

A common mistake is to omit a `break` statement to end each case. In the preceding example, if the `break` statement after the `Screen.write("B")` statement were omitted, the computer would print both "B" and "C", since the interpreter executes commands until a `break` statement is encountered.

Normally, if a `switch` and series of case statements reference array variables, then a comparison is performed whether or not the reference the same array data. But if either the `switch` variable or one of the case values is a literal string, then the comparison of the strings is done using the values of the strings in a `Clib.strcmp()` type of comparison.

## goto and labels

You may jump to any location within a function block by using the `goto` statement. The syntax is:

```
goto LABEL;
```

where `label` is an identifier followed by a colon (:). The following code fragment continuously prompts for a number until a number less than 2 is entered.

```
beginning:
Screen.write("Enter a number less than 2:")
var x = getche(); //get a value for x
if (a >= 2)
    goto beginning;
Screen.write(a);
```

As a rule, `goto` statements should be used sparingly, since they make it difficult to track program flow.

## Conditional operator

The conditional operator, "`? :`", provides a shorthand method for writing if statements. It is harder to read than conventional if statements, and so is generally used when the expressions in the if statements are brief. The syntax is:

```
test_expression ? expression_if_true : expression_if_false
```

First, `test_expression` is evaluated. If `test_expression` is non-zero, `true`, then `expression_if_true` is evaluated, and the value of the entire expression replaced by the value of `expression_if_true`. If `test_expression` is `false`, then `expression_if_false` is evaluated, and the value of the entire expression is that of `expression_if_false`.

The following fragment illustrates the use of the conditional operator.

```
foo = ( 5 < 6 ) ? 100 : 200; // foo is set to 100
Screen.write("Name is " + ((null==name) ? "unknown" : name));
```

---

## Exception handling

Exception handling statements consist of: **throw**, **try**, **catch**, and **finally**. The concept of exception handling includes dealing with unusual results in a function and with errors and recovery from them. Exception handling that uses the `try` related statements is most useful with complex error handling and recovery. Testing for simple errors and unwanted results is usually handled most easily with familiar `if` or `switch` statements. In this section, the discussion and examples deal with simple situations, since explanation and illustration are the goals. The exception handling statements might seem clumsy or bulky here, but do not lose sight of the fact that they are very powerful and elegant in real world programming where error recovery can be very complex and require much code when using traditional statements.

Another advantage of using `try` related exception handling is that much of the error trapping code may be in a function rather than in all the places that call a function.

Before getting to specifics, here is some generalized phrasing that might help working with exception handling statements. A function may have code in it to

detect unusual results and to **throw an exception**. The function is called from inside a **try** statement block which will **try to run the function** successfully. If there is a problem in the function, the exception thrown is **caught and handled** in a **catch** statement block. If all exceptions have been handled when execution reaches the **finally** statement block, the **final code is executed**.

Remember these execution guides:

- When a `throw` statement executes, the rest of the code in a function is ignored, and the function does not return a value.
- A program continues in the next `catch` statement block after the `try` statement block in which an exception occurred., and any value thrown is caught in a parameter in the `catch` statement.
- A program executes a `finally` statement block if all thrown exceptions have been caught and handled.

`catch` will receive an error object that can be printed directly as a string, and which will contain these properties

- `name` - Name of the exception class, e.g. "ConversionError"
- `message` - text of error, e.g. "1607: Variable "b" is undefined."
- `fileName` - Name of the source file where error occurred, if available, e.g. "c:\foo\myscript.jsa"
- `lineNum` - Line number if file where error occurred, if available, e.g. "173"
- `functionName` - Name of executing function where error occurred, if available, e.g. "foobar"

The following simple script illustrates all exception handling statements. The **main() function** has `try`, `catch`, and `finally` statement blocks. The `try` block calls `SquareEven()`, which throws an exception if an odd number is passed to it. If an even number is passed to the function, then the number is squared and returned. If an odd number is passed, it is fixed, and an exception is thrown. When the `throw` statement executes, it passes an object, as an argument, with information for the `catch` statement to use.

For example, the script below, as shown, displays:

```
16
We caught odd and squared even.
```

If you change `rtn = SquareEven(4)` to `rtn = SquareEven(3)`, the display is:

```
Fixed odd number to next higher even. 16
We caught odd and squared even.
```

```
function main(argc, argv)
{
    var rtn;

    try
    {
        rtn = SquareEven(4);
        // No display here if number is odd
        Screen.writeln(rtn);
    }
}
```

```

catch (err)
{
    // Catch the exception info
    // that was thrown by the function.
    // In this case, the info was returned
    // in an object.
    Screen.writeln(err);
    Screen.write("Error occurred at line " + err.lineNum );
    if ( err.fileName )
        Screen.write(" of file " + err.fileName );
    if ( err.functionName )
        Screen.writeln(" in function " + err.functionName );
    Screen.writeln("");
}
finally
{
    // Finally, display this line after normal processing
    // or exceptions have been caught.
    Screen.writeln("We caught odd and squared even.");
}

Screen.write("Paused..."); Clib.getch();
} //main

// Check for odd integers
// If odd, make even, simplistic by adding 1
// Square even number
function SquareEven(num)
{
    // Catch an odd number and fix it.
    // "throw an exception" to be caught by caller
    if ((num % 2) != 0)
    {
        num += 1;
        throw {msg:"Fixed odd number to next higher even. ",
              rtn:num * num};

        // We throw an object here. We could have thrown
        // a primitive, such as:
        // throw("Caught and odd");
        // We would have to alter the catch statement
        // to expect whatever data type is used.
    }
    // Normal return for an even number.
    return num * num;
} //SquareEven

```

This example script does not actually handle errors. Its purpose is to illustrate how exception handling statements work. For purposes of this illustration, assume that an odd number being passed to `SquareEven()` is an error or extraordinary event.

---

## Functions

A function is an independent section of code that receives information from a program and performs some action with it. Once a function has been written, you do not have to think again about how to perform the operations in it. Just call the function, and let it handle the work for you. You only need to know what information the function needs to receive, that is, the parameters, and whether it returns a value to the statement that called it.

Screen.write() is an example of a function which provides an easy way to display formatted text. It receives a string from the function that called it and displays the string on the screen. Screen.write is a void function, meaning it has no return value.

In JavaScript, functions are considered a data type, evaluating to whatever the function's return value is. You can use a function anywhere you can use a variable. Any valid variable name may be used as a function name. Like comments, using descriptive function names helps you keep track of what is going on with your script.

Two things set functions apart from the other variable types: instead of being declared with the "var" keyword, functions are declared with the "function" keyword, and functions have the function operator, "()", following their names. Data to be passed to a function is included within these parentheses.

Several sets of built-in functions are included as part of the ScriptEase interpreter. These functions are described in this manual. They are internal to the interpreter and may be used at any time. In addition, ScriptEase ships with a number of external libraries or .jsh files. External libraries must be explicitly included in your script to use the functions in them. See the description of the include directive in the preprocessor.

ScriptEase allows you to have two functions with the same name. The interpreter uses the function nearest the end of the script, that is, the last function to load is the one that to be executed when the function name is called. By taking advantage of this behavior, you can write functions that supersede the ones included in the interpreter or .jsh files.

## Function return statement

The return statement passes a value back to the function that called it. Any code in a function following the execution of a return statement is not executed.

```
function DoubleAndDivideBy5(a)
{
    return (a*2)/5
}
```

Here is an example of a script using the above function.

```
function main()
{
    var a = DoubleAndDivideBy5(10);
    var b = DoubleAndDivideBy5(20);
    Screen.write(a + b);
}
```

This script displays12.

## Passing information to functions

JavaScript uses different methods to pass variables to functions, depending on the type of variable being passed. Such distinctions ensure that information gets to functions in the most complete and logical ways. To be technically correct, the data that is passed to a function are called arguments, and the variables in a function definition that receive the data are called parameters.

Primitive types, namely, strings, numbers, and booleans, are passed by value. The value of these variables are passed to a function. If a function changes one of these variables, the changes will not be visible outside of the function where the change took place.

Composite types, objects and arrays, are passed by reference. Instead of passing the value of the object, that is, the values of each property, a reference to the object is passed. The reference indicates where in a computer's memory that values of an object's properties are stored. If you make a change in a property of an object passed by reference, that change will be reflected throughout in the calling routine.

In ScriptEase it is possible to pass primitive types by reference instead of by value, which is the default. When a function is defined, an ampersand, &, may be put in front of one or more of its parameters. Thus, when the function is called, an argument, corresponding to a parameter with an ampersand, is passed by reference instead of by value. The following fragment illustrates.

```
var num1 = 4;
var num2 = 4;
var num3;
SetNumbers(num1, num2, num3, 6)

function SetNumbers(&n1, n2, &n3, &n4)
{
    n1 = n2 = n3 = n4 = 5;
}
```

After executing this code, the values of variables is:

```
num1 == 5
num2 == 4
num3 == 5
```

The variable num1 was passed by reference to parameter n1. When n1 was set to 5, num1 was actually set to 5 since n1 merely pointed to num1. The variable num2 was passed by value to parameter n2. When n2, which received an actual value of 4, was set to 5, num2 remained unchanged. The variable num3 was undefined when passed by reference to parameter n3. When n3, which pointed to num3, was set to 5, num3 was actually set to 5 and defined as an integer type. The literal value 6 was passed to parameter n4, but not by reference since 6 is not a variable that can be changed. Though n4 has an ampersand, the literal value 6 was passed by value to n4 which, in this example, becomes merely a local variable for the function SetNumbers().

## Simulated named parameters

The properties of object data types may be used like named parameters. The following line simulates named parameters in a call to a function (note the use of curly braces {}):

```
var area = RectangleArea({length:4, width:2});
```

The following line uses traditional ordered parameters:

```
var area = RectangleArea(4, 2);
```

The following function definition receives the named and ordered parameters in the lines above. The definition allows for named or ordered parameters to be used.

```
function RectangleArea(length, width)
{
    if (typeof(length) == "object")
    {
        width = length.width;
        length = length.length;
    }
    return length * width;
} //RectangleArea
```

The function above could be rewritten as:

```
function RectangleArea(length, width)
{
    if (typeof(arguments[0]) == "object")
    {
        width = arguments[0].width;
        length = arguments[0].length;
    }
    return length * width;
} //RectangleArea
```

Either function definition works the same. The choice of one over the other is a matter of personal preference.

Though JavaScript allows many variations in how objects may be used, this straightforward example illustrates the essence of simulating named parameters in JavaScript. See the section "Named parameters in JavaScript" in the *ScriptEase Tutorial* for a detailed discussion about simulating named parameters in JavaScript.

## Function property arguments[]

The `arguments[]` property is an array of all of the arguments passed to a function. The first variable passed to a function is referred to as `arguments[0]`, the second as `arguments[1]`, and so forth.

The most useful aspect of this property is that it allows you to have functions with an indefinite number of parameters. Here is an example of a function that takes a variable number of arguments and returns the sum of them all.

```
function SumAll()
{
    var total = 0;
    for (var ssk = 0; ssk < SumAll.arguments.length; ssk++)
    {
        total += SumAll.arguments[ssk];
    }
    return total;
}
```

## Function recursion

A recursive function is a function that calls itself or that calls another function that calls the first function. Recursion is permitted in ScriptEase. Each call to a function is independent of any other call to that function. (See the section on

**variable scope**.) Be aware that recursion has limits. If a function calls itself too many times, a script will run out of memory and abort.

Do not worry if recursion is confusing, since you rarely have to use it. Just remember that a function can call itself if it needs to. For example, the following function, `factor()`, factors a number. Factoring is an ideal candidate for recursion because it is a repetitive process where the result of one factor is then itself factored according to the same rules.

```
function factor(i) // recursive function to print all factors of
i,
{ // and return the number of factors in i
  if ( 2 <= i )
  {
    for ( var test = 2; test <= i; test++ )
    {
      if ( 0 == (i % test) )
      {
        // found a factor, so print this factor then call
        // factor() recursively to find the next factor
        return( 1 + factor(i/test) );
      }
    }
  }
  // if this point was reached, then factor not found
  return( 0 );
}
```

## Error checking for functions

Some functions return a special value if they fail to do what they are supposed to do. For example, the `Clib.fopen()` method opens or creates a file for a script to read from or write to. But suppose that the computer is unable to open a file. In such a case, the `Clib.fopen()` method returns `null`.

If you try to read from or write to a file that was not properly opened, you get all kinds of errors. To prevent these errors, make sure that `Clib.fopen()` does not return `null` when it tries to open a file. Instead of just calling `Clib.fopen()` as follows:

```
var fp = Clib.fopen("myfile.txt", "r");
```

check to make sure that `null` is not returned:

```
if (null == (var fp = Clib.fopen("myfile.txt", "r")))
{
  ErrorMsg("Clib.fopen returned null");
}
```

You may abort a script in such a case, but at least you will know why. See the section on the **Clib object**.

## main() function

If a script has a function called `main()`, it is the first function executed. (For more information on what takes place when a script is run, see the section on running a script.) Other than the fact that `main()` is the first function executed, it is like other functions. If the `main()` function returns a value, that value is returned to the operating system or whatever process called the script.

The `main()` function automatically receives two parameters, which, by convention, are called `argc` and `argv`. The parameter `argc`, argument count, is the number of parameters passed to the script and the parameter `argv` is an array of strings, with each element being one of the parameters. The first element, `argv[0]`, of this array is always the name of the script, thus if `argc == 1`, then no variables were passed to a script.

Arguments are passed to a script as parameters when it is called from a command line as illustrated in the following line.

```
sewin32.exe jseedit.jse document.txt
```

In the example above, `argc == 2`, `argv[0] == "jseedit.jse"` and `argv[1] == "document.txt"`.

---

## Objects

Variables and functions may be grouped together in one variable and referenced as a group. A compound variable of this sort is called an object in which each individual item of the object is called a property. In general, it is adequate to think of object properties, which are variables or constants, and of object methods, which are functions.

To refer to a property of an object, use both the name of the object and of the property, separated by the object operator ".", a period. Any valid variable name may be used as a property name. For example, the code fragment below assigns values to the width and height properties of a rectangle object and calculates the area of a rectangle and displays the result:

```
var Rectangle;  
  
Rectangle.height = 4;  
Rectangle.width = 6;  
  
Screen.write(Rectangle.height * Rectangle.width);
```

The main advantage of objects occurs with data that naturally occurs in groups. An object forms a template that can be used to work with data groups in a consistent way. Instead of having a single object called `Rectangle`, you can have a number of `Rectangle` objects, each with their own values for width and height.

## Terminology for objects

The terminology used to describe the methods and properties of objects is not consistent in the programming community. The following list shows three common naming schemes.

- Object members  
Object methods  
Object properties
- Object properties  
Object methods  
Object attributes

- Object properties  
Object methods  
Object properties

In the first scheme uses "members" as the term to encompass "methods" and "properties". The second scheme uses "properties" as the term to encompass "methods" and "attributes". The third scheme uses "properties" as the term to encompass "methods" and "properties". The order in which the schemes are presented is in order from least ambiguous to most ambiguous. Unfortunately this order does not conform to age of use of the schemes nor to the popularity of the schemes. As a result of the lack of consensus in the programming community, all of these naming schemes are represented in ScriptEase documentation, though the first one is preferred because it is not ambiguous. The following paragraphs explain these schemes in more detail.

The first scheme uses the term "member" for the both functions and data. A "method" is a function attached to an object and a "property" is a datum attached to an object. This scheme has the advantages of being clear and of using common terminology. The disadvantage is that the use of "members" to refer to "methods" and "properties" is not the most common. This scheme is preferred in ScriptEase documentation for a couple of reasons. First, objects are thought of as collections of routines and data, which is an intuitive and useful metaphor for describing objects. The term "member" fits nicely with the metaphor and is distinct from the terms for items in the collection. Second, the use of the terms "method" and "property" for the routines and data attached to or collected in an object is the most common usage.

The second scheme uses the term "property" for the both functions and data. A "method" is a function attached to an object and an "attribute" is a datum attached to an object. This scheme has the advantages of being clear and of using common terminology. The disadvantage is that the use of "attributes" for the data of objects is not the most common.

The third scheme uses the term "property" for the both functions and data. A "method" is a function attached to an object and a "property" is a datum attached to an object. This scheme is inherently confusing because it uses the same term "property" for two different concepts about an object.

## Predefining objects with constructor functions

A constructor function creates an object template. For example, a constructor function to create Rectangle objects might be defined like the following.

```
function Rectangle(width, height)
{
    this.width = width;
    this.height = height;
}
```

The keyword `this` is used to refer to the parameters passed to the constructor function and can be conceptually thought of as "this object." To create a Rectangle object, call the constructor function with the "new" operator:

```
var joe = new Rectangle(3,4)
var sally = new Rectangle(5,3);
```

This code fragment creates two rectangle objects: one named joe, with a width of 3 and a height of 4, and another named sally, with a width of 5 and a height of 3.

Constructor functions create objects belonging to the same class. Every object created by a constructor function is called an instance of that class. The examples above creates a Rectangle class and two instances of it. All of the instances of a class share the same properties, although a particular instance of the class may have additional properties unique to it. For example, if we add the following line:

```
joe.motto = "ad astra per aspera";
```

we add a motto property to the Rectangle joe. But the rectangle sally has no motto property.

## Initializers for objects and arrays

Variables may be initialized as objects and arrays using lists inside of "{}" and "[]". By using these initializers, instances of Objects and Arrays may be created without using the new constructor. Objects may be initialized using a syntax similar to the following:

```
var o = {a:1, b:2, c:3};
```

This line creates a new object with the properties a, b, and c set to the values shown. The properties may be used with normal object syntax, for example, o.a == 1.

Arrays may be initialized using a syntax similar to the following:

```
var a = [1, 2, 3];
```

This line creates a new array with three elements set to 1, 2, and 3. The elements may be used with normal array syntax, for example, a[0] == 1.

The distinction between Object and Array initializer might be a bit confusing when using a line with syntax similar to the following:

```
var a = {1, 2, 3};
```

This line also creates a new array with three elements set to 1, 2, and 3. The line differs from the first line, Object initializer, in that there are no property identifiers and differs from the second line, Array initializer, in that it uses "{}" instead of "[]". In fact, the second and third lines produce the same results. The elements may be used with normal array syntax, for example, a[0] == 1.

The following code fragment shows the differences.

```
var o= {a:1, b:2, c:3};
Screen.writeln(typeof o +" | "+ o._class +" | "+ o);

var a = [1, 2, 3];
Screen.writeln(typeof a +" | "+ a._class +" | "+ a);

var a= {1, 2, 3};
Screen.writeln(typeof a +" | "+ a._class +" | "+ a);
```

The display from this code is:

```
object | Object | [object Object]
object | Array | 1,2,3
```

```
object | Array | 1,2,3
```

As shown in the first display line, the variable `o` is created and initialized as an Object. The second and third lines both initialize the variable `a` as an Array. Notice that in all cases the `typeof` of the variable is `object`, but the class, which corresponds to the particular object and which is reflected in the `_class` property, shows which specific object is created and initialized.

## Methods - assigning functions to objects

Objects may contain functions as well as variables. A function assigned to an object is called a method of that object.

Like a constructor function, a method refers to its variables with the `this` operator. The following fragment is an example of a method that computes the area of a rectangle.

```
function rectangle_area()  
{  
    return this.width * this.height;  
}
```

Because there are no parameters passed to it, this function is meaningless unless it is called from an object. It needs to have an object to provide values for `this.width` and `this.height`.

A method is assigned to an object as the following lines illustrates.

```
joe.area = rectangle_area;
```

The function will now use the values for height and width that were defined when we created the rectangle object `joe`.

Methods may also be assigned in a constructor function, again using the `this` keyword. For example, the following code:

```
function rectangle_area()  
{  
    return this.width * this.height;  
}  
  
function Rectangle(width, height)  
{  
    this.width = width;  
    this.height = height;  
    this.area = rectangle_area;  
}
```

creates an object class `Rectangle` with the `rectangle_area` method included as one of its properties. The method is available to any instance of the class:

```
var joe = Rectangle(3,4);  
var sally = Rectangle(5,3);  
  
var area1 = joe.area;  
var area2 = sally.area;
```

This code sets the value of `area1` to 12, and the values of `area2` to 15.

## Object prototypes

An object prototype lets you specify a set of default values for an object. When an object property that has not been assigned a value is accessed, the prototype is consulted. If such a property exists in the prototype, its value is used for the object property.

Object prototypes are useful for two reasons: they ensure that all instances of an object use the same default values, and they conserve the amount of memory needed to run a script. When the two Rectangles, joe and sally, were created in the previous section, they were each assigned an area method. Memory was allocated for this function twice, even though the method is exactly the same in each instance. This redundant memory waste can be avoided by putting the shared function or property in an object's prototype. Then all instances of the object will use the same function instead of each using its own copy of it.

The following fragment shows how to create a Rectangle object with an area method in a prototype.

```
function rectangle_area()
{
    return this.width * this.height;
}

function Rectangle(width, height)
{
    this.width = width;
    this.height = height;
}

Rectangle.prototype.area = rectangle_area;
```

The `rectangle_area` method can now be accessed as a method of any Rectangle object as shown in the following.

```
var area1 = joe.area();
var area2 = sally.area();
```

You can add methods and data to an object prototype at any time. The object class must be defined, but you do not have to create an instance of the object before assigning it prototype values. If you assign a method or data to an object prototype, all instances of that object are updated to include the prototype.

If you try to write to a property that was assigned through a prototype, a new variable will be created for the newly assigned value. This value will be used for the value of this instance of the object's property. All other instances of the object will still refer to the prototype for their values. If, for the sake of this example, we assume that joe is a special Rectangle, whose area is equal to three times its width plus half its height, we can modify joe as follows.

```
joe.area = function joe_area()
{
    (this.width * 3) + (this.height/2);
}
```

This fragment creates a value, which in this case is a function, for `joe.area` that supercedes the prototype value. The property `sally.area` is still the default value defined by the prototype. The instance joe uses the new definition for its area method.

## for/in

The `for/in` statement is a way to loop through all of the properties of an object, even if the names of the properties are unknown. The statement has the following form.

```
for (var property in object)
{
    DoSomething(object[property]);
}
```

where `object` is the name of an object previously defined in a script. When using the `for . . . in` statement in this way, the statement block will execute once for every property of the object. For each iteration of the loop, the variable `property` contains the name of one of the properties of `object` and may be accessed with "`object[property]`". Note that properties that have been marked with the `DontEnum` attribute are not accessible to a `for . . . in` statement.

`SElib.getObjectProperties()` is similar to the ECMAScript `for/in` loop. The important difference is that a `for/in` loop does not enumerate properties that have `DONT_ENUM` as part of their attributes (`global.setAttributes()`), whereas `SElib.getObjectProperties()` includes them in the array that it returns. See `Object.propertyIsEnumerable()`.

## with

The `with` statement is used to save time when working with objects. It lets you assign a default object to a statement block, so you need not put the object name in front of its properties and methods. The object is automatically supplied by the interpreter. The following fragment illustrates using the `Clib` object.

```
with (Clib)
{
    printf("I am a camera");
    srand();
    xxx = rand() % 5;
    putchar(xxx);
}
```

The `Clib` methods, `Clib.printf()`, `Clib.srand()`, `Clib.rand()`, and `Clib.putchar()`, in the sample above are called as if they had been written with `Clib` prefixed. All code in the block following a `with` statement seems to be treated as if the methods associated with the object named by the `with` statement were global functions. Global functions are still treated normally, that is, you do not need to prefix "global." to them unless you are distinguishing between two like-named functions common to both objects.

If you were to jump, from within a `with` statement, to another part of a script, the `with` statement would no longer apply. In other words, the `with` statement only applies to the code within its own block, regardless of how the interpreter accesses or leaves the block.

You may not use `goto` and `labels` to jump into or out of the middle of a `with` statement block.

## \_construct(...)

This method is called whenever a new object is created with the new operator. The object will have been already created and passed as the this variable to the .construct() method.

## **\_call(...)**

The call function is called whenever an object method is called. Whatever parameters are passed to the original function will be passed to the call() function.

The following example creates an Annoying object that beeps whenever it retrieves the value of a property.

```
function myget(prop)
{
    System.beep();
    return this[property];
}

var Annoying = new Object;

Annoying.get = myget;
```

Note that the System.beep() method is used only for this example and must be explicitly created for actual use.

# ScriptEase versus C language

This section is primarily for those who already know how to program in C, though novice programmers can learn more about the Clib and SELib objects and C concepts by reading it. The emphasis is on those elements of ScriptEase that differ from standard C. Most of the pertinent differences involve the **Clib object**, **SELib object**, and **CString object**. Users who are not familiar with C should first read the section on ScriptEase JavaScript.

The assumption here is that readers of this section already know C. Thus, only those aspects of the C portion of ScriptEase that differ from C are described. If something is not mentioned here, ScriptEase follows standard C behavior. While in this section on the differences from C, the term ScriptEase is used for the portion of ScriptEase that implements the standard C library and ScriptEase additions to that library. Almost all of the implementation of C in ScriptEase involves the use of Clib objects, SELib objects, or CString. Thus, references to ScriptEase as the C portion of ScriptEase usually involve Clib, SELib, or CString.

Deviations from C result from following several principles:

- simplicity
- power
- safety

The C portion of ScriptEase is different from C where changes make ScriptEase more convenient for scripting, writing small programs, and entering command line code or where unaltered C rules encourage coding that is potentially unsafe. Keep in mind, that most issues involved in this section involve the use of Clib, SELib, and CString.

The C portion of ScriptEase is C without type declarations and pointers. If you already know C and can forget these two aspects of C while using ScriptEase, then you already know the C portion of ScriptEase. If you were to take C code and delete all the lines, code words, and symbols that either declare data types or explicitly point to data, then you would be left with code that would work with Clib, SELib, and CString. Though you would be altering source code, you would not be removing capabilities.

The most basic idea underlying this section is that the C portion of ScriptEase is C without type declarations and pointers.

---

## Data types in C and SE

ScriptEase uses the same data types as JavaScript.

---

## Automatic type declaration

There are no type declarations nor type castings as found in C. Types are determined from context. In the statement, `var i = 6`, the variable `i` is a number type. For example, the following C code:

```
int max(int a, int b)
{
```

```

    int result;
    result = (a < b) ? b : a;
    return result;
}

```

could be converted to the following ScriptEase code:

```

Clib.max(a, b)
{
    var result = (a < b) ? b : a;
    return result;
}

```

The code could be made even more like C by using a with statement as in the following fragment.

```

with (Clib)
{
    max(a, b)
    {
        var result = (a < b) ? b : a;
        return result;
    }
}

```

A with statement can be used with large blocks of code which would allow Clib and SELib methods to be called like C functions. C programmers will appreciate this ability. Other users who decide to use the extra power of C functions will come to appreciate this ability.

---

## Array representation

This section on the representation of arrays in memory only deals with automatic arrays which are part of the C portion of ScriptEase. JavaScript uses constructor functions that create instances of JavaScript arrays which are actually objects more than arrays. Everything said in this section is about automatic arrays compared to C arrays. The methods and functions used to work with JavaScript constructed arrays and ScriptEase automatic arrays are different. The following fragment creates a JavaScript array.

```

var aj = new Array();

```

The following line creates an automatic array in ScriptEase.

```

var ac[3][3];

```

The two arrays are different entities that require different methods and functions. For example, the property `aj.length` provides the length of the `aj` array, but the function `getArrayLength(ac)` provides the length of the `ac` automatic array. When the term array is used in the rest of this section, the reference is to an automatic array. JavaScript arrays are covered in the section on ScriptEase JavaScript.

Arrays are used in ScriptEase much like they are in C, except that they are stored differently. A single dimension array, for example, an array of numbers, is stored in consecutive bytes in memory, just as in C, but arrays of arrays are not in consecutive memory locations. The following C declaration:

```

char c[3][3]; // this is the C version

```

indicates that there are nine consecutive bytes in memory. In ScriptEase a similar statement such as the following:

```
var c[2][2] = 'a'; // this is the ScriptEase version
```

indicates that there are at least three arrays of characters, and the third array of arrays has at least three characters in it. Though the characters in `c[0]` and the characters in `c[1]` are in consecutive bytes, the two arrays `c[0]` and `c[1]` are not necessarily adjacent in memory.

---

## Automatic array allocation

Arrays are dynamic, and any index, positive or negative, into an array is always valid. If an element of an array is referenced, then ScriptEase ensures that such an element exists. For example, if a statement in a script is:

```
var foo[4] = 7;
```

then ScriptEase makes an array of 5 integers referenced by the variable `foo`. If a later statement refers to `foo[6]` then ScriptEase expands `foo`, if necessary, to ensure that the element `foo[6]` exists. The same is `true` for negative indices. When `foo[- 10]` is referenced, `foo` is grown in the negative direction if necessary, but `foo[4]` still refers to the initial 7. Arrays can be of any order of dimensions, thus `foo[6][7][34][- 1][4]` is a valid variable or array.

---

## Automatic and JavaScript Arrays

C style automatic arrays have just been discussed. Perhaps some simple and direct comparisons of the two different kinds of arrays would be helpful.

The following lines of code create an automatic array of 3 elements:

```
var a;  
a[0] = 0;  
a[1] = "one";  
a[2] = 2;
```

The following line of code creates an automatic array consisting of objects that have information about files in the root directory of drive C. See [SElib.directory\(\)](#). Several functions from the C library objects, `Clib` and `SElib`, return automatic arrays.

```
var a = SElib.directory("c:\\*.");
```

The following two lines of code both produce identical JavaScript arrays of 3 elements each.

```
var a = new Array(0, "one", 2);  
var a = [0, "one", 2];
```

The following lines of code also produce a JavaScript array which is identical to the two immediately preceding arrays:

```
var a = new Array();  
a[0] = 0;  
a[1] = "one";  
a[2] = 2;
```

The elements of automatic and JavaScript arrays are accessed in the same way using indices, for example:

```
a[3] = "three";
Screen.writeln(a[3]);
```

These lines behave the same for both automatic and JavaScript arrays. But what are some of the differences? The following fragment:

```
var aa;
aa[0] = 0;
aa[1] = "one";

var ja = [0, "one"];

Screen.writeln(typeof(aa));
Screen.writeln(typeof(ja));

Screen.writeln(aa._class);
Screen.writeln(ja._class);
```

results in the following display:

```
object
object
Object
Array
```

which shows that both automatic and JavaScript arrays are of type `object`. But automatic arrays belong to the `Object` class and JavaScript arrays belong to the `Array` class. See `array.jsh - arrays and objects` for more information on the differences. The `Array` class inherits the properties of the `Object` class but the `Object` class does not have the properties of the `Array` class. What does that mean?

Instances of both automatic arrays and JavaScript arrays may use the properties and methods of the `Object` class, but only JavaScript arrays may use the properties of the `Array` class. For example and using the two arrays defined immediately above, the `length` property of the `Array` class may only be used with the JavaScript array `ja`, that is, `var len = ja.length` is valid but `var len = aa.length` is an error. To get the length of `aa`, an automatic array, the function `global.getArrayLength()` must be used with it. As just explained, the JavaScript array `ja` may also be used with the function. That is, both of the following are valid: `getArrayLength(aa)` and `getArrayLength(ja)`.

Having both types of arrays is a result of providing the C standard library in the `Clib` and `SElib` objects. If you want to simplify matters use the `Object.convert()` method to convert arrays from one class to the other. In general, if you convert automatic arrays to JavaScript arrays and work only with JavaScript arrays, your scripting will be simpler and more powerful. But, remember, if you are only going to do simple things with arrays, then working with either class of array is quick and simple.

---

## Literal strings

A literal string in `ScriptEase` is any array of characters, that is, a string, appearing in source code within double, single, or back quotes. Back quotes are sometimes

referred to as back-ticks. The following lines show examples of literal strings in ScriptEase:

```
"dog"           // literal string (double quote)
'dog'          // literal string (single quotes)
`dog`          // literal string (back-ticks)
{'d','o','g','\0'} // not a literal string, rather
                // an array initialization
```

Literal strings have special treatment for certain ScriptEase operations for the following reasons.

- To protect literal string data from being overwritten accidentally
- To reduce confusion for novice programmers who do not think of strings as arrays of bytes
- To simplify writing code for common operations, for example, the statement:

```
TestStr == "MYLONGPASSWORD"
```

is simpler than :

```
Clib.strcmp(TestStr, "MYLONGPASSWORD").
```

In general, literal strings adhere to the two following rules.

- Comparisons are intrinsically handled by **Clib.strcmp()**
- Assignment and passing of literal strings is done by making copies of the literal string

## Literal strings and assignments

When a literal string is assigned to a variable, a copy is made of the string, and the variable is assigned the copy of the literal string. For example, the following code:

```
for (var i = 0; i < 3; i++)
{
    var str = "dog";
    Clib.strcat(str, "house");
    Clib.puts(str);
}
```

results in the following output:

```
doghouse
doghouse
doghouse
```

A strict C interpretation of this code would not only overwrite memory, but would also generate the following output:

```
doghouse
doghousehouse
doghousehousehouse
```

## Literal strings and comparisons

If both sides of a comparison operator are strings, and at least one of them is a literal string, then the comparison is performed as if **Clib.strcmp()** were being

used. If one or both variables are literal strings, then the following translation of the comparison operation is performed.

```
lvar operator rvar    Clib.strcmp(lvar, rvar) operator 0
```

The following examples demonstrate how literal strings follow the logic of `Clib.strcmp()`.

```
if (animal == "dog") // if (Clib.strcmp(animal, "dog") == 0)
if (animal < "dog")  // if (Clib.strcmp(animal, "dog") < 0)
if ("dog" <= animal) // if (Clib.strcmp("dog", animal) <= 0)
```

In ScriptEase, the following fragment:

```
var animal = "dog";
if (animal == "dog")
  Clib.puts("hush puppy");
```

displays:

```
"hush puppy"
```

## Literal strings and parameters

When a literal string is a parameter to a function, it is passed as a copy, that is, by value. For example, the following code:

```
for (var i = 0; i < 3; i++)
{
  var str = Clib.strcat("dog", "house");
  Clib.puts(str)
}
```

results in the following output:

```
doghouse
doghouse
doghouse
```

## Literal strings and returns

When a literal string is returned from a function by a return statement, it is returned as a copy of the string. The following code:

```
for (var i = 0; i < 3; i++)
{
  var str = Clib.strcat(dog(), "house");
  Clib.puts(str)
}

function dog()
{
  return "dog";
}
```

results in the following output:

```
doghouse
doghouse
doghouse
```

## Literal Strings and switch statements

If either a switch expression or a case expression is a literal string, then the case statement match is based on a string comparison using `Clib.stremp()` logic. The following fragment illustrates.

```
switch(Clib.strlwr(temp, argv[1]))
{
case "add":
{
    DoTheAddThing();
    break;
}
case "remove":
{
    DoTheRemoveThing();
    break;
}
default:
{
    Clib.puts("Whaddya want?");
}
}
```

---

## Structures

Structures are created dynamically, and their elements are not necessarily contiguous in memory. When ScriptEase encounters a statement such as:

```
foo.animal = "dog"
```

it creates a structure element of `foo` that is referenced by `"animal"` and that is an array of characters. The `"animal"` variable becomes an element of the `"foo"` variable. Though `foo`, in this example, may be thought of and used as a structure and `animal` as an element, in actuality, `foo` is a JavaScript object and `animal` is a property. The resulting code looks like regular C code, except that there is no separate structure definition anywhere. The following C code:

```
struct Point
{
    int Row;
    int Column;
}

struct Square
{
    struct Point BottomLeft;
    struct Point TopRight;
}

void main()
{
    struct Square sq;
    int Area;
    sq.BottomLeft.Row = 1;
    sq.BottomLeft.Column = 15;
    sq.TopRight.Row = 82;
    sq.TopRight.Column = 120;
    Area = AreaOfASquare(sq);
}

int AreaOfASquare(struct Square s)
```

```

{
    int width, height;
    width = s.TopRight.Column - s.BottomLeft.Column + 1;
    height = s.TopRight.Row - s.BottomLeft.Row + 1;
    return( width * height );
}

```

can be easily converted into ScriptEase code as shown in the following.

```

function main()
{
    var sq.BottomLeft.Row = 1;
    sq.BottomLeft.Column = 15;
    sq.TopRight.Row = 82;
    sq.TopRight.Column = 120;
    var Area = AreaOfASquare(sq);
}

function AreaOfASquare(s)
{
    var width = s.TopRight.Column - s.BottomLeft.Column + 1;
    var height = s.TopRight.Row - s.BottomLeft.Row + 1;
    return( width * height );
}

```

Structures can be passed, returned, and modified just as any other variable. Of course, structures and arrays are different and independent, which allows a statement like the following.

```
foo[8].animal.forge[3] = bil.bo
```

Some operations, such as addition, are not defined for structures.

---

## Passing variables by reference

By default, lvalues in ScriptEase are passed to functions by value (that is, the function cannot alter the lvalue) . But if a variable is declared in a function with the "&" symbol then it is passed by reference. If a function alters a pass-by-reference (i.e. &argument) variable, then the variable passed as an argument by the calling routine is altered also, if it is an lvalue. So instead of the following C code which uses address and pointer operators:

```

main()
{
    CQuadrupleInPlace(&i);
    ...
}

void CQuadrupleInPlace(int *j)
{
    *j += 4;
}

```

a ScriptEase conversion could be:

```

function main()
{
    ...
    QuadrupleInPlace(i);
    ...
}

```

```
function QuadrupleInPlace(&j)
{
    j += 4;
}
```

The following calls to QuadrupleInPlace() are valid in ScriptEase, but the values passed as arguments are not changed after QuadrupleInPlace() is called. Why? None of the arguments being passed are lvalues.

```
QuadrupleInPlace(8);
QuadrupleInPlace(i+1);
QuadrupleInPlace(8+1);
```

---

## Pointer operator \* and address operator &

No pointers. None. The \* symbol never means pointer in ScriptEase, which might cause seasoned C programmers to gasp in disbelief. But the situation turns out not to be such a big deal. The pointer operator is easily replaced. For example, \*var can be replaced by var[0].

Because it is common in C to use address arithmetic on string, ScriptEase provides the CString object, which provides most of the array and address functionality of a C string pointer. The following function displays the string in the variable s. In the first display line shows:

```
abcde
```

The second display line, which uses address arithmetic "s+2" shows:

```
cde
```

```
function main(argc, argv)
{
    var s = new CString("abcde");
    Screen.writeln(s);
    Screen.writeln(s+2);
}
```

Remember that in functions, all variables, except primitive data types, are passed by reference. ScriptEase adds the address operator & for primitive data types. If you want to pass a primitive data type by reference in a JavaScript function, use the address operator in the parameter list. For example,

```
function SetNumbers(&n1, n2, &n3, &n4)
{
    n1 = n2 = n3 = n4 = 5;
}
```

---

## Case statements

Case statements in a switch statement may be constants, variables, or other statements that can be evaluated to a value. The following switch statement has case statements which are valid in ScriptEase.

```
switch(i)
```

```

{
  case 4:
  case foe():
  case "thorax":
  case Math.sqrt(foe()):
  case (PILLBOX * 3 - 2):
  default:
}

```

As described in the section on literal strings above, if either a switch expression or a case expression is a literal string, then any comparisons are based on the logic of `Clib.strcmp()`, that is, as if the comparisons were `!Clib.strcmp(switch_expr, case_expr)`.

---

## Initialization code which is external to functions

All code not inside a function block is interpreted before `main()` is called and can be thought of as initialization code. When a script has initialization code outside of functions and code inside of functions, it shares characteristics of both batch and program scripts. Thus, the following ScriptEase code:

```

Clib.printf("first ");

function main()
{
  Clib.printf("third.");
}

Clib.printf("second ");

```

results in the following output:

```

first second third.

```

---

## Unnecessary tokens

If symbols are redundant, they are usually unnecessary in ScriptEase which allows more flexibility in writing scripts and is less onerous for users not trained in C. Semicolons that end statements are usually redundant and do not do anything extra when a script is interpreted. C programmers are trained to use semicolons to end statements, a practice that can be followed in ScriptEase. Indeed, some programmers think that the use of semicolons in ScriptEase and JavaScript is a good to be pursued. Many people who are not trained in C wonder at the use of redundant semicolons and are sometimes confused by their use. The use of semicolons is personal. If a programmer wants to use them, then he should, but if he does not want to, then he should not.

In ScriptEase the two statements, `"foo ()"` and `"foo ();"` are identical. It does not hurt to use semicolons, especially when used with return statements, such as `"return;"`. But widespread or regular use of semicolons simply is not necessary. Similarly, parentheses, `"(" and ")"`, are often unnecessary. For example, the following fragment is valid and results in both of the variables, `n` and `x`, being equal to 7.

```

var n = 1 + 2 * 3 var x = 2 * 3 + 1

```

The following fragment is identical and is clearer, but it requires more typing because of the addition of redundant tokens.

```
var n = 1 + (2 * 3); var x = (2 * 3) + 1;
```

The fragments could be rewritten to be:

```
var n = 1 + 2 * 3
var x = 2 * 3 + 1
```

and:

```
var n = 1 + (2 * 3);
var x = (2 * 3) + 1;
```

Which fragment is better? The answer depends on personal taste. Efforts to standardize programming styles over the last three decades have been abysmal failures, not unlike efforts to control the Internet.

---

## Macros

Function macros are not supported. Since speed is not of primary importance in a scripting language, a macro gains little over a function call. Macros simply become functions.

---

## Token replacement macros

The `#define` preprocessor directive, which can be thought of and used as a macro, is supported by ScriptEase. As an example, the following token replacement is recognized and implemented during the preprocessing phase of script interpretation.

```
#define NULL 0
```

---

## Back quote strings

Back quotes are not used at all for strings in the C language. The back quote character, ```, also known as a back-tick or grave accent, may be used in ScriptEase in place of double or single quotes to specify strings. However, strings that are delimited by back quotes do not translate escape sequences. For example, the following two lines describe the same file name:

```
"c:\\autoexec.bat" // traditional C method, which is also
                  // valid in ScriptEase
`c:\\autoexec.bat` // alternative ScriptEase method
```

---

## Converting existing C code to ScriptEase

Converting existing C code to ScriptEase is mostly a process of deleting unnecessary text. Type declarations, such as *int*, *float*, *struct*, *char*, and `[]`, should be deleted. The following two columns give examples of how to make such changes. C code is on the left and can be replaced by the ScriptEase code on the right.

## C

```
int i;
int foo = 3;
struct
{
    int row;
    int col;
}
char name[] = "George";
int goo(int a, char *s, int c);
int zoo[] = {1, 2, 3};
```

## ScriptEase

```
var i; // or nothing
var foo = 3;
var st; // no struct type
    // Simply use st.row
    // and st.col
    // when needed.
var name = "George";
var goo(a, buf, c);
var zoo = {1, 2, 3};
```

Another step in converting C to ScriptEase is to search for pointer and address operators, \* and &. Since the \* operator and & operator work together when the address of a variable is passed to a function, these operators are unnecessary in the C portion of ScriptEase. If code has \* operators in it, they usually refer to the base value of a pointer address. A statement like `*foo = 4` can be replaced by `foo[0] = 4`.

Finally, the `->` operator in C which is used with **structures** may be replaced by a period for values passed by address and then by reference.

# Security

As a scripting language, ScriptEase provides the power to completely control a computer system. But there are times when this power can be dangerous. Many applications, such as those using distributed scripting, might need to run scripts that you do not want to have access to all of the power of ScriptEase. You do not want these scripts to delete files on your machine, read and transmit important data to a remote machine, execute arbitrary system programs, or any other such activities. ScriptEase security allows you to limit scripts so they cannot do these things.

ScriptEase security works by dividing functions on the system into **secure functions**, those which can perform no dangerous actions, and **insecure functions**, those which can perform dangerous activities. When you execute a script, you can attach a security manager to it. This manager will determine which insecure functions can be called.

If the script tries to call an insecure function which the manager does not allow, it will not call the function but will generate a security error. By using ScriptEase security, you can run scripts you trust and give them full access to dangerous functions, such as `Clib.system()` and `Clib.remove()`, while denying access to these same functions to other scripts you do not trust.

---

## Writing a Security Manager

Whenever you wish to interpret a script, via the API using `jseInterpret()` or in a script using `SElib.interpret()`, you can attach a security manager to the child script that you are running. As long as that child script calls other functions only within that script, it is allowed to do so. If it tries to call an insecure function, your security gets called. Obviously, insecure wrapper functions are always checked.

In the case of a script using `SElib.interpret()` to interpret a child script, that child may be able to try to call functions in the parent. Since the security you added only applies to the child script, the functions in your original script are also considered insecure to the child. The child must get permission to call them exactly like it would need to get permission to call an insecure wrapper function directly.

You can think of your security manager as a big wall with a heavily guarded door. As long as the script stays on its side of the wall, it is fine. The parent script and all wrapper functions are on the other side of the wall. If the child script wants to get access to them, it must convince the guards to let it through.

Let's look at the pieces that make up these security guards.

### **jseSecurityInit**

This function is the main security function. It is run before the script that it is protecting is run, and it sets up the security the child is going to be run under. It specifies which functions the child will be allowed to call. By default, the child will not be allowed to call any insecure functions. In this function, you explicitly specify which insecure functions the child will be allowed to call. You do this by

calling the `setSecurity()` method, which is a method of all `ScriptEase` functions.

In case that is confusing, a quick example of a `jseSecurityInit` function should clear it up:

```
function jseSecurityInit(security_var)
{
    Clib.remove.setSecurity(jseSecureAllow);
}
```

This particular security initialization function is written in `ScriptEase` script. However, you can also implement all of these functions using the `ScriptEase` API and wrapper functions. We will implement the examples as scripts for clarity. The first thing you notice about the function is that it takes a parameter, we have named it `security_var`. We did not use it in this example. This parameter is the "security variable" described below."

The body of the function usually lists which functions are to be allowed. Notice that we call the `setSecurity()` method of the particular function we want to allow. This method takes one parameter, the security state of the function.

`jseSecureAllow` specifies that this function is allowed to be called.

There are two other values we could have used instead. The value `jseSecureReject` causes calls to the function to fail. This is the default for all functions, so it is usually redundant to specify it. However, if `setSecurity()` is called more than once for the same function, the last call takes precedence. You can use this value to undo allowing access to a particular function.

The final value is `jseSecureGuard`, which says that any time this function is called, we must first call the `jseSecurityGuard` function to determine if the call will be allowed. This function is described below.

**Note:** The `setSecurity()` method can only be called in a security initialization function. Trying to call it at other times generates errors.

## **jseSecurityTerm**

Whenever you have an initialization function, you have a corresponding termination function. Like `jseSecurityInit`, this function gets a single parameter, the security variable (described below.) This function is rarely needed, and you can simply not specify it most of the time. It is included so that you can clean up the security variable before exiting. You do not need to *unset* the `setSecurity()` calls done, as the engine knows that they go away when they are no longer used. The security termination function looks like this:

```
function jseSecurityTerm(security_var)
{
    /* do any necessary cleanup */
}
```

This function is not usually called until the end of the program (not just the end of the script.) Why is this? For `ISDK` developers, if you have read the advanced concepts chapter, you know that all of the functions in a `jseInterpret()` stick around in the global object, even after the `jseInterpret()` call itself is

finished. This is why you can *load* functions using `jseInterpret()` and later call them. Whatever security they had when they were created is not forgotten.

All functions remember the security in effect when they were created, and that applies if they are again called later. So, the security termination function is not actually called until all of the functions have gone away, which happens at the end of the program when the ScriptEase engine cleans up everything.

## jseSecurityGuard

Usually it is enough to specify which functions you want to allow to be called in the `jseSecurityInit` function and leave it at that. There can be cases in which you want to allow a function to be called with certain parameters but reject it with others. For instance, you may want to limit creating sockets to certain ports or limit opening files to certain filenames. You specify `jseSecureGuard` for the `setSecurity()` options for these functions, and before they can be called, your `jseSecurityGuard` function will first be called to validate this call.

Here is an example:

```
function jseSecurityGuard(security_var, func, filename)
{
    if( func==Clib.fopen )
    {
        /* get the full path so the user can't trick us with
        * something like: 'c:\\temp\\..\\windows\\win.ini'
        */
        var actualname = SElib.fullpath(filename);

        /* We only want to allow files in this directory
        *to be opened.
        */
        return Clib.strnicmp("c:\\temp\\",actualname,8)==0;
    }
    else
    {
        return false;
    }
}
```

This function, like the other two, gets the security variable as its first parameter. Again, we will describe that shortly. The second parameter is the actual function being called. In this example, we compare it to `Clib.fopen()` so that we can validate a call to `Clib.fopen()`. The security guard function must return `true` to allow the call or `false` to disallow it. In this case, we return `false` if it is not `Clib.fopen()`. Presumably, we only label `Clib.fopen()` as `jseSecureGuard`, so only `Clib.fopen()` will be using this guard function.

We include the `else` clause because it is always a good idea to cover all bases. If it is something we do not expect, we just say no. This is good programming practice in general. If the parameters are not what you expect, even if you think it is impossible for them not to be, still do something sensible even if that turns out not to be the case.

Notice that this function has a third parameter, `filename`. All of the parameters that are being passed to the called function are also passed to the security guard function after the two parameters it always gets. The first parameter to the called function is the third to security guard, the second we receive as our fourth, and so

on. This allows us to examine the parameters that the function will get when deciding if we want to allow the call. In fact, there would be little point in not examining the parameters. If we are always going to reject or accept a particular call regardless of the parameters, we can instead just set that up in the `jseSecurityInit` function.

Perceptive readers will note that `Clib.fopen()` actually takes two parameters, but we have only named one of them. In JavaScript, you can pass extra parameters to script functions, more than are named in the parameter list. These parameters are still there and can be accessed using the `arguments` object. In this case, `filename` is the same as `arguments[2]`, and we could have referred to it that way. The file mode parameter to `Clib.fopen()` will also be passed to us. We can refer to it as `arguments[3]`, or we can name it in the parameter list if we need to check it as well.

This example checks the name and only allows file access in the `C:\temp\` directory. We could limit it in any way we choose, this is just one possibility.

## securityVariable

We mentioned above that each function gets a security variable passed to it. Each security manager has a single variable associated with it. You can specify this when you specify your security functions (see below for specifying security). Alternately, if you do not, a blank `ScriptEase` object is created (as if calling `new Object()`) and used. This variable cannot be accessed by the script being run, but it is passed to each security function whenever it is called. This allows you to store data needed to implement your security and keep it safe from the script being run.

---

## Specifying Security

The `ScriptEase` API call `jseInterpret()` has among its settings `jseNewSecurity`. If you turn this on, then the script being run will have security applied to it. If you leave it off, no security applies and all functions can be called. The four security items we just finished discussing correspond to the four fields of the `jseExternalLinkParameters` structure of the same name. Before you interpret the script, you use `jseGetExternalLinkParameters()` to get the parameters structure, fill in these fields, then call `jseInterpret()` with the `jseNewSecurity` flag turned on. You must fill in the `jseSecurityInit` function. If you do not, the `jseNewSecurity` flag will be ignored.

Since the parameters are `jseVariables`, you set them to any function you like. You can use `jseCreateWrapperFunction()` to create a wrapper function to do the security tasks. In the example above, we used script examples. `ScriptEase Desktop` implements security this way. The three functions are put in a script. You tell `ScriptEase Desktop` the name of the script using the command line parameter `/secure=<security script name>`. `ScriptEase Desktop` interprets that script first, picks out the security functions, and uses them when it interprets the script you are really interested in. The functions in the security script must be given the names we described above.

When you interpret a script from within a script, using `SElib.interpret()`, you can also specify the security for that child script. See the manual description of `SElib.interpret()` for details on how you do this.

---

## Wrapper Functions And Security

Wrapper functions are insecure because they are labeled that way. When you write your own wrapper functions and add them using `jseAddLibrary()`, you get to label them as either secure or insecure. Remember, if there is any possible way the function could be misused, make it insecure. If you are in doubt about whether a particular function should be labeled secure or insecure, choose insecure.

When you are writing a wrapper function, it is possible for it to use `jseCallFunction()` or `jseInterpret()` to execute more code. These calls are affected by security. This allows security to propagate. For instance, the ECMAScript function `eval()` executes a text string as script code exactly like the text string appeared directly in the script. In this case, the wrapper acts just as a pass through, and the code it executes should follow all of the standard security rules. In fact, the ECMAScript `eval()` function itself is secure; whatever text it executes has the same security as what was already executing. ScriptEase uses this model when you use these two API calls. As a result, the following behavior applies:

When calling a function using `jseCallFunction()`, the call is treated as if the wrapper function's caller was making the call. This means that the calling script function will need to get approval to call the new function. Typically, a wrapper function that just turns around and uses `jseCallFunction()` is itself secure.

`jseInterpret()` has different behavior depending on the wrapper function itself. If the wrapper function is insecure, then the script run with `jseInterpret()` starts with no security. If the wrapper function is secure, then `jseInterpret()` starts with the same security as the calling function.

So, for instance, ECMAScript `eval()` is secure as we already mentioned. Thus, when it runs a new script, that script has the existing security restrictions still on it. If the function was labeled insecure, then it has already passed a security check to be able to call it, and it can continue to do dangerous things, so any scripts it interprets are likewise at this high level of security. `jseInterpret()` allows security to be added using the `jseNewSecurity` flag. This is on top of whatever security it already has as specified above.

---

## Sample Script

Here is a sample ScriptEase Desktop security script. If you use it, then the desktop scripts will not be allowed to use any insecure functions except a few file-related ones. In addition, `Clib.fopen()` will only be allowed to open files in the `C:\temp\` directory.

```
function jseSecurityInit(security_var)
{
    /* allow basic file manipulations, but nothing fancy, and
    * make sure to examine all open calls very carefully.
```

```

    */
    Clib.fopen.setSecurity(jseSecureGuard);
    Clib.fclose.setSecurity(jseSecureAllow);
    Clib.fprintf.setSecurity(jseSecureAllow);
    Clib.fread.setSecurity(jseSecureAllow);
    Clib.fwrite.setSecurity(jseSecureAllow);
}

function jseSecurityGuard(security_var, func, filename)
{
    /* we only guard the fopen call, so this should be it */
    Clib.assert( security_var==Clib.fopen );

    /* get the full path so the user can't trick us with something
    * like: 'c:\\temp\\..\\windows\\win.ini'
    */
    var actualname = SElib.fullpath(filename);

    /* We only want to allow files in this directory to be opened.
    */
    return Clib.strnicmp("c:\\temp\\",actualname,8)==0;
}

```

# Internal Objects

See:

- Global object
- Array object

- Boolean Object
- Buffer Object
- Clib Object
- Date Object
- Dos Object
- Function Object
- Math Object
- Number Object
- Object Object
- RegExp Object
- SLib Object
- String Object
- Unix Object

---

## Global object

The properties and methods of the `global` object may be thought of as global variables and functions. The object identifier `global` is not required when invoking a `global` method or function. Indeed, the object name generally is not used. For example, the following two `if` statements are identical, but the first one illustrates how `global` functions are usually invoked.

```
if (defined(name))
    Screen.writeln("name is defined");

if (global.defined(name))
    Screen.writeln("name is defined");
```

The following two lines of code are also equivalent.

```
var aString = ToString(123)
var aString = global.ToString(123)
```

Remember, global variables are members of the global object. To access global properties, you do not need to use an object name. The exception to this rule occurs when you are in a function that has a local variable with the same name as a global variable. In such a case, you must use the `global` keyword to reference the global variable.

Most of the `global` methods, functions, described in this section are defined in the ECMAScript standards. A few are unique additions to ScriptEase. In other words, they are not part of the ECMAScript standard, but they are useful. Avoid using the unique functions in a script if it will be used with a JavaScript interpreter that does not support these few unique functions.

## Conversion or casting

Though ScriptEase does well in automatic data conversion, there are times when the types of variables or data must be specified and controlled. Each of the following casting functions, the functions below that begin with "To", has one parameter, which is a variable or piece of data, to be converted to or cast as the data type specified in the name of the function. For example, the following fragment creates two variables.

```
var aString = ToString(123);
var aNumber = ToNumber("123");
```

The first variable `aString` is created as a string from the number 123 converted to or cast as a string. The second variable `aNumber` is created as a number from the string "123" converted to or cast as a number. Since `aString` had already been created with the value "123", the second line could also have been:

```
var aNumber = ToNumber(aString);
```

The type of the variable or piece of data passed as a parameter affects the returns of some of these functions.

---

### **global.\_argc**

SYNTAX: `_argc`

DESCRIPTION: This property refers to the number of parameters passed to the

---

---

`main()` function of a script. The name of the script is always the first parameter, so if `_argc == 1`, then the script received no arguments. See the [main\(\) function](#) for more information on `argc` and the `main()` function. General programming practice uses `argc`, a parameter to the `main()` function rather than `_argc`.

SEE: [main\(\) function](#), [global.\\_argv](#)

EXAMPLE: 

```
function main(argc, argv)
{
    // At this point, unless deliberately changed
    // by special programming, _argc == argc
}
```

---

## **global.\_argv**

---

SYNTAX: `_argv`

DESCRIPTION: This property is an array of strings. Each string is a parameter passed to the `main()` function. The value of `argv[0]` is always the name of the script being called. The first parameter passed to the script is in `argv[1]`. See the [main\(\) function](#) for more information on `argc`, `argv`, and the `main()` function. General programming practice uses `argv`, a parameter to the `main()` function rather than `_argv`.

SEE: [main\(\) function](#), [global.\\_argc](#)

---

## **global object methods/functions**

### **global.defined()**

---

SYNTAX: `defined(value)`

WHERE: `value` - a value or variable to check to see if it is defined.

RETURN: boolean - `true` if the value has been defined, else `false`

DESCRIPTION: This function tests whether a variable, object property, or value has been defined. The function returns `true` if a value has been defined, or else returns `false`. The function `defined()` may be used during script execution and during preprocessing. When used in preprocessing with the directive `#if`, the function `defined()` is similar to the directive `#ifdef`, but is more powerful. The following fragment illustrates three uses of `defined()`.

SEE: [global.undefine\(\)](#), [in operator](#), [undefined](#)

EXAMPLE: 

```
var t = 1;
#if defined(_WIN32_)
    Screen.writeln("in Win32");
    if (defined(t))
        Screen.writeln("t is defined");
    if (!defined(t.t))
        Screen.writeln("t.t is not defined");
#endif
```

---

---

```
// The first use of defined() checks whether a value
// is available to the preprocessor
// to determine which platform is running the script.
// The second use checks a variable "t".
// The third use checks an object "t.t"
```

---

## **global.escape()**

---

**SYNTAX:** `escape(str)`

**WHERE:** `str` - with special characters that need to be handled specially, that is, escaped.

**RETURN:** string - with special characters escaped or fixed so that the string may be used in special ways, such as being a URL.

**DESCRIPTION:** The `escape()` method receives a string and escapes the special characters so that the string may be used with a URL. This escaping conversion may be called encoding. All uppercase and lowercase letters, numbers, and the special symbols, `@ * + - . /`, remain in the string. All other characters are replaced by their respective unicode sequence, a hexadecimal escape sequence. This method is the reverse of `global.unescape()`.

**SEE:** [global.unescape\(\)](#), `String escape()`

**EXAMPLE:**

```
escape("Hello there!");
// Returns "Hello%20there%21"
```

---

## **global.eval()**

---

**SYNTAX:** `eval(expression)`

**WHERE:** `expression` - a valid expression to be parsed and treated as if it were code or script.

**RETURN:** value - the result of the evaluation of expression as code.

**DESCRIPTION:** Evaluates whatever is represented by the parameter expression. If expression is not a string, it will be returned. For example, calling `eval(5)` returns the value 5.

If expression is a string, the interpreter tries to interpret the string as if it were JavaScript code. If successful, the method returns the last variable with which was working, for example, the return variable. If the method is not successful, it returns the special value, `undefined`.

**SEE:** [SElib.interpret\(\)](#)

**EXAMPLE:**

```
var a = "who";
// Displays the string as is
Screen.writeln('a == "who"');
// Evaluates the contents of the string as code,
// and displays "true",
// the result of the evaluation
Screen.writeln(eval('a == "who"'));
```

---

## **global.isFinite()**

---

SYNTAX:	<code>isFinite(number)</code>
WHERE:	<code>number</code> - to check if it is a finite number.
RETURN:	boolean - if the parameter is or can be converted to a number, else <code>false</code> .
DESCRIPTION:	This method returns <code>true</code> if the parameter, <code>number</code> , is or can be converted to a number. If the parameter evaluates as <code>NaN</code> , <code>Number.POSITIVE_INFINITY</code> , or <code>Number.NEGATIVE_INFINITY</code> , the method returns <code>false</code> .
SEE:	<a href="#">global.isNaN()</a>
EXAMPLE:	<pre>if (isFinite(99)) Screen.writeln("A number");</pre>

---

### **global.isNaN()**

---

SYNTAX:	<code>isNaN(number)</code>
WHERE:	<code>number</code> - a value to if it is not a number.
RETURN:	boolean - <code>true</code> if <code>number</code> is not a number, else <code>false</code> .
DESCRIPTION:	This method returns <code>true</code> if the parameter, <code>number</code> , evaluates to <code>NaN</code> , "Not a Number". Otherwise it returns <code>false</code> .
SEE:	<a href="#">global.isFinite()</a>
EXAMPLE:	<pre>if (isNaN(99)) Screen.writeln("Not a number");</pre>

---

### **global.getLength()**

---

SYNTAX:	<code>getLength(array[, minIndex])</code>
WHERE:	<code>array</code> - an automatic array.  <code>minIndex</code> - the minimum index to use.
RETURN:	number - the length of an array.
DESCRIPTION:	<p>This function should be used with dynamically created arrays, that is, with arrays that were <b>not</b> created using the <code>new Array()</code> operator and constructor. When working with arrays created using the <code>new Array()</code> operator and constructor, use the <code>length</code> property of the <code>Array</code> object. The <code>length</code> property is not available for dynamically created arrays which must use the functions, <code>global.getLength()</code> and <code>global.setLength()</code>, when working with array lengths.</p> <p>The <code>getLength()</code> function returns the length of a dynamic array, which is one more than the highest index of an array, if the first element of the array is at index 0, which is most common. If the parameter <code>minIndex</code> is passed, then it is used to set to the minimum index, which will be zero or less. You can use this function to get the length of an array that was not created with the <code>Array()</code> constructor function.</p> <p>This function and its counterpart, <code>setLength()</code>, are intended for use with dynamically created arrays, that is, arrays not created with the <code>Array()</code> constructor function. Use the</p>

---

---

**Array length** property to get the length of arrays created with the constructor function and not `getArrayLength()`.

SEE: [global.setArrayLength\(\)](#), [Array length](#)

EXAMPLE: 

```
// automatic object array
var arr;
arr[0] = "zero";
arr[1] = 1;
arr[2] = 2;
Screen.writeln(getArrayLength(arr)); // 3

// JavaScript Array object
var arr = ["zero", 1, 2]
Screen.writeln(arr.length); // 3
```

---

### **global.getAttributes()**

---

SYNTAX: `getAttributes(variable)`

WHERE: `variable` - a variable identifier, name.

RETURN: `number` - representing the attributes set for a variable. If no attributes are set, the return is 0. See [global.setAttributes\(\)](#) for a list of predefined constants for the attributes that a variable may have.

DESCRIPTION: Gets and returns the variable attributes for the parameter variable. Variable attributes may be set using the function `setAttributes()`. See [global.setAttributes\(\)](#) for more information and descriptions of the attributes of variables that can be set.

SEE: [global.setAttributes\(\)](#)

---

### **global.parseFloat()**

---

SYNTAX: `parseFloat(str)`

WHERE: `str` - to be converted to a decimal float.

RETURN: `number` - the float to which the string converts, else NaN.

DESCRIPTION: This method is similar to [global.parseInt\(\)](#) except that it reads decimal numbers with fractional parts. In other words, the first period, ".", in the parameter string is considered to be a decimal point, and any following digits are the fractional part of the number. The method `parseFloat()` does not take a second parameter.

SEE: [global.parseInt\(\)](#)

EXAMPLE: 

```
var i = parseInt("9.3");
```

---

### **global.parseInt()**

---

SYNTAX: `parseInt(str[, radix])`

WHERE: `str` - to be converted to an integer.

`radix` - the number base to use, default is 10.

---

---

**RETURN:** number - the integer to which string converts, else NaN.

**DESCRIPTION:** This method converts an alphanumeric string to an integer number. The first parameter, `str`, is the string to be converted, and the second parameter, `radix`, is an optional number indicating which base to use for the number. If the `radix` parameter is not supplied, the method defaults to base 10, which is decimal. If the first digit of string is a zero, `radix` defaults to base 8, which is octal. If the first digit is zero followed by an "x", that is, "0x", `radix` defaults to base 16, which is hexadecimal.

White space characters at the beginning of the string are ignored. The first non-white space character must be either a digit or a minus sign (-). All numeric characters following the string will be read, up to the first non-numeric character, and the result will be converted into a number, expressed in the base specified by the `radix` variable. All characters including and following the first non-numeric character are ignored. If the string is unable to be converted to a number, the special value NaN is returned.

**SEE:** [global.parseFloat\(\)](#)

**EXAMPLE:**

```
var i = parseInt("9");
var i = parseInt("9.3");
// In both cases, i == 9
```

---

### **global.setArrayLength()**

---

**SYNTAX:** `setArrayLength(array[, minIndex[, length]])`

**WHERE:** `array` - may be an array, buffer, or string. Though there are multiple ways to set length on these data types, `setArrayLength()` may be used on all three.

`minIndex` - the minimum index to use. Default is 0.

`length` - the length of the array to set.

**RETURN:** void.

**DESCRIPTION:** This function sets the first index and length of an array. Any elements outside the bounds set by `MinIndex` and `length` are lost, that is, become `undefined`. If only two arguments are passed to `setArrayLength()`, the second argument is `length` and the minimum index of the newly sized array is 0. If three arguments are passed to `setArrayLength()`, the second argument, which must be 0 or less, is the minimum index of the newly sized array, and the third argument is the length.

**SEE:** [global.getArrayLength\(\)](#), [Array length](#), [Blob.size\(\)](#)

**EXAMPLE:**

```
#include <string.jsh>

var arr = [4,5,6,7];
Screen.writeln(getArrayLength(arr));
setArrayLength(arr, 5);
// arr is now [4,5,6,7,,];

/*****
```

---

---

The examples below illustrate using `setArrayLength()` with:  
arrays  
strings  
buffers

When appropriate alternatives exist for setting length, they are shown as comments.

These examples are not 100% exhaustive, but show most ways to use `setArrayLength()`.  
\*\*\*\*\*/

```
// Two ways to create an array
// with 5 undefined elements
var a1 = new Array();
setArrayLength(a1, 5);
//a1.length = 5      // Does the same

var a2 = [];
setArrayLength(a2, 5);
//a2.length = 5      // Does the same

// Two ways to create a string
// of five "\0" characters
var s1 = "\0".repeat(5);

var s2 = "";
setArrayLength(s2, 5);

// Three ways to create a buffer
// of five "\0" characters
var b1 = new Buffer(s1);

var b2 = new Buffer(5);

var b3 = new Buffer(5);
setArrayLength(b3, 5);
//Blob.size(b3, 5);    // Does the same
//b3.length = 5;      // Does the same
```

---

## **global.setAttributes()**

---

SYNTAX: `setAttributes(variable, attributes)`

WHERE: `variable` - a variable identifier, name.

`attributes` - the attribute or attributes to be set for a variable. If more than one attribute is being set, use the or operator, "|", to combine them.

RETURN: `void`.

DESCRIPTION: This function sets the variable attributes for the parameter variable using the parameter attributes. Variables in ScriptEase may have various attributes set that affect the behavior of variables. This function has no return.

The following list describes the attributes that may be set for variables. Multiple attributes may be set for variables by combining them with the or operator. For example, the flag `setting READ ONLY | DONT ENUM` sets both of these attributes

---

---

for one variable.

- **DONT\_DELETE**  
This variable may not be deleted. If the delete operator is used with a variable, nothing is done.
- **DONT\_ENUM**  
This variable is not enumerated when using a for/in loop.
- **IMPLICIT\_PARENTS**  
This attribute applies only to local functions and allows a scope chain to be altered based on the `__parent__` property of the "this" variable. If this flag is set, if the `__parent__` property is present, and if a variable is not found in the local variable context, activation object, of a function, then the parents of the "this" variable are searched backwards before searching the global object. The example below illustrates the effect of this flag.
- **IMPLICIT\_THIS**  
This attribute applies only to local functions. If this flag is set, then the "this" variable is inserted into a scope chain before the activation object. For example, if variable `TestVar` is not found in a local variable context, activation object, the interpreter searches the current "this" variable of a function.
- **READ\_ONLY**  
This variable is read-only. Any attempt to write to or change this variable fails.

SEE: [global.getAttributes\(\)](#)

EXAMPLE:

```
// The following fragment illustrates the use
// of setAttributes() and the behavior affected
// by the IMPLICIT_PARENTS flag.
function foo()
{
    value = 5;
}
setAttributes(foo, IMPLICIT_PARENTS)

var a;
a.value = 4;
var b;
b.__parent__ = a;
b.foo = foo;
b.foo();

// After this code is run, a.value is set to 5.
```

---

## **global.ToBoolean()**

---

SYNTAX: `ToBoolean(value)`

WHERE: `value` - to be cast as a boolean.

RETURN: `boolean` - conversion of value.

DESCRIPTION: The following list indicates how different data types are converted by this function.

- `Boolean`
-

---

same as value

- Buffer  
same as for String
  - null  
false
  - Number  
false, if value is 0, +0, -0 or NaN, else true
  - Object  
true
  - String  
false if empty string, "", else true
  - undefined  
false
- 

### **global.ToBuffer()**

---

SYNTAX: ToBuffer(value)

WHERE: value - to be cast as a buffer.

RETURN: buffer - conversion of value.

DESCRIPTION: This function converts value to a buffer in a manner similar to [global.ToString\(\)](#) except that the resulting array of characters is a sequence of ASCII bytes and not a unicode string.

SEE: [global.ToBytes\(\)](#)

---

### **global.ToBytes()**

---

SYNTAX: ToBytes(value)

WHERE: value - to be cast as a buffer.

RETURN: buffer - conversion of value.

DESCRIPTION: This function converts value to a buffer and differs from [global.ToBuffer\(\)](#) in that the conversion is actually a raw transfer of data to a buffer. The raw transfer does not convert unicode values to corresponding ASCII values. For example, the unicode string "Hit" is stored in a buffer as "\0H\0\i\0t", that is, as the hexadecimal sequence: 00 48 00 69 00 74.

SEE: [global.ToBuffer\(\)](#)

---

### **global.ToInt32()**

---

SYNTAX: ToInt32(value)

WHERE: value - to be cast as a signed 32-bit integer.

RETURN: number - conversion of value.

DESCRIPTION: This function is the same as [global.ToInteger\(\)](#) except that if the return is an integer, it is in the range of  $-2^{31}$  through  $2^{31} - 1$ .

SEE: [global.ToInteger\(\)](#), [global.ToNumber\(\)](#)

---

---

## **global.ToInteger()**

---

SYNTAX: `ToInteger(value)`

WHERE: `value` - to be cast as an integer.

RETURN: `number` - conversion of value.

DESCRIPTION: This function converts `value` to an integer type. First, call [global.ToNumber\(\)](#). If result is `NaN`, return `+0`. If result is `+0`, `-0`, `+Infinity` or `-Infinity`, return result. Else return `floor(abs(result))` with the appropriate sign. For example, the value `-4.8` is converted to `-4`.

SEE: [global.ToInt32\(\)](#), [global.ToNumber\(\)](#)

---

---

## **global.ToNumber()**

---

SYNTAX: `ToNumber(value)`

WHERE: `value` - to be cast as a number.

RETURN: `number` - conversion of value.

DESCRIPTION: The following table lists how different data types are converted by this function.

- `Boolean`  
`+0`, if value is `false`, else `1`
- `Buffer`  
same as for `String`
- `null`  
`+0`
- `Number`  
same as value
- `Object`  
first, call `ToPrimitive()`, then call `ToNumber()` and return result
- `String`  
number, if successful, else `NaN`
- `undefined`  
`NaN`

SEE: [global.ToInteger\(\)](#), [global.ToInt32\(\)](#)

---

---

## **global.ToObject()**

---

SYNTAX: `ToObject(value)`

WHERE: `value` - to be cast as an object.

RETURN: `object` - conversion of value.

DESCRIPTION: The following table lists how different data types are converted by this function.

- `Boolean`  
new `Boolean` object with value
  - `null`
-

- 
- generate runtime error
  - Number  
new Number object with value
  - Object  
same as parameter
  - String  
new String object with value
  - undefined  
generate runtime error

SEE: [global.ToPrimitive\(\)](#)

---

### **global.ToPrimitive**

---

SYNTAX: `ToPrimitive(value)`  
WHERE: `value` - to be cast as a primitive.  
RETURN: `value` - conversion of `value` to one of the primitive data types.  
DESCRIPTION: This function does conversions only for parameters of type Object. An internal default value of the Object is returned.  
SEE: [global.ToObject\(\)](#)

---

### **global.ToSource()**

---

SYNTAX: `ToSource(value)`  
WHERE: `value` - a variable or value to convert to a source string that will reproduce `value` when the string is evaluated or interpreted.  
RETURN: `string` - a string representation of `value`, which can be evaluated or interpreted.  
DESCRIPTION: A variable or value may be represented by a string comprised of JavaScript statements which, when evaluated or interpreted, reproduce the variable or value. The source string may be evaluated by [global.eval\(\)](#) or by [SElib.interpret\(\)](#). It is sometimes convenient or powerful to use source strings, for example, in the Data object the [DSP object](#).

Though the source string may be read by humans, it is daunting. Remember, `ToSource()` is designed for interpretation by the ScriptEase interpreters, not by users.

The example below compares source strings created by the `global.ToSource()` function and the [Object.toSource\(\)](#) method. In these examples, the source strings are identical, which is not guaranteed always to be so. But, no matter which one is used, the source strings can be evaluated or interpreted.

SEE: [Object.toSource\(\)](#), [global.eval\(\)](#), [SElib.interpret\(\)](#)

EXAMPLE: 

```
// An Array
var a = [1, '2', 3];

Screen.writeln(ToSource(a));
```

---

---

```

Screen.writeln();
Screen.writeln(a.toString());
Screen.writeln();
/*****
Displays:

((new Function("var tmp1 = [1,\"2\",3]; tmp1[\"0\"] =
1;
tmp1[\"1\"] = \"2\"; tmp1[\"2\"] = 3; return
tmp1;"))())

((new Function("var tmp1 = [1,\"2\",3]; tmp1[\"0\"] =
1;
tmp1[\"1\"] = \"2\"; tmp1[\"2\"] = 3; return
tmp1;"))())
*****/

// An Object
var o = {one:1, two:'2', three:3};

Screen.writeln(ToSource(o));
Screen.writeln();
Screen.writeln(o.toString());
Screen.writeln();
/*****
Displays:

((new Function("var tmp1 = new Object();
tmp1[\"three\"] = 3;
tmp1[\"one\"] = 1; tmp1[\"two\"] = \"2\"; return
tmp1;"))())

((new Function("var tmp1 = new Object();
tmp1[\"three\"] = 3;
tmp1[\"one\"] = 1; tmp1[\"two\"] = \"2\"; return
tmp1;"))())
*****/

```

---

## **global.ToString()**

SYNTAX:	ToString(value)
WHERE:	value - to be cast as a string.
RETURN:	string - conversion of value.
DESCRIPTION:	<p>The following table lists how different data types are converted by is this function.</p> <ul style="list-style-type: none"> <li>• Boolean "false", if value is false, else "true"</li> <li>• null "null"</li> <li>• Number if value is NaN, return "NaN". If +0 or -0, return "0". If Infinity, return "Infinity". If a number, return a string representing the number. If a number is negative, return "-" concatenated with the string representation of the number.</li> <li>• Object first, call ToPrimitive(), then call ToString() and return result</li> </ul>

---

- 
- String  
same as value
  - undefined  
"undefined"

SEE: [global.ToPrimitive\(\)](#), [global.ToNumber\(\)](#)

---

### **global.ToUint16()**

---

SYNTAX: `ToUint16(value)`

WHERE: value - to be cast as a 16 bit unsigned integer.

RETURN: number - conversion of value.

DESCRIPTION: This function is the same as [global.ToInteger\(\)](#) except that if the return is an integer, it is in the range of 0 through  $2^{16} - 1$ .

SEE: [global.ToUint32\(\)](#), [global.ToInteger\(\)](#)

---

### **global.ToUint32()**

---

SYNTAX: `ToUint32(value)`

WHERE: value - to be cast as a 32 bit unsigned integer.

RETURN: number - conversion of value.

DESCRIPTION: This function is the same as [global.ToInteger\(\)](#) except that if the return is an integer, it is in the range of 0 through  $2^{32} - 1$ .

SEE: [global.ToInt32\(\)](#), [global.ToInteger\(\)](#)

---

### **global.unescape()**

---

SYNTAX: `unescape(str)`

WHERE: str - holding escape characters.

RETURN: string - with escape characters replaced by appropriate characters.

DESCRIPTION: This method is the reverse of the [global.escape\(\)](#) method and removes escape sequences from a string and replaces them with the relevant characters. That is, an encoded string is decoded.

SEE: [global.escape\(\)](#), `String.unescape()`

EXAMPLE: 

```
unescape("Hello%20there%21");  
// Returns "Hello there!"
```

---

### **global.undefine()**

---

SYNTAX: `undefine(value)`

WHERE: value - value, variable, or property to be undefined.

RETURN: void.

DESCRIPTION: This function undefines a variable, Object property, or value. If a value was previously defined so that its use with the function [global.defined\(\)](#) returns `true`, then after using `undefine()`

---

---

with the value, `defined()` returns `false`. undefining a value is different than setting a value to `null`.

The **delete operator** may be used only with properties of objects and elements of arrays and is more complete than `undefine()`. Two other techniques, using **undefined** and `void`, are equivalent to `undefine()`. The following three techniques for undefining `test` are equivalent:

```
var test = 111;

undefine(test);
test = undefined;
test = void test;
```

SEE: [global.defined\(\)](#), [delete operator](#), [undefined](#)

EXAMPLE:

```
// In the following fragment, the variable n
// is defined with the number value of 2 and
// then undefined.
var n = 2;
undefine(n);

// In the following fragment an object o
// is created and a property o.one is defined.
// The property is then undefined but
// the object o remains defined.
var o = new Object;
o.one = 1;
undefine(o.one);
```

---

---

# Array object

An Array object is an object in JavaScript and is in the underlying ECMAScript standard. Be careful not to confuse an array variable that has been constructed as an instance of the Array object with the automatic or dynamic arrays of ScriptEase. ScriptEase offers automatic arrays in addition to the Array object of ECMAScript. The purpose is to ease the programming task by providing another easy to use tool for scripters. The current section is about Array objects.

An Array is a special class of object that refers to its properties with numbers rather than with variable names. Properties of an Array object are called elements of the array. The number used to identify an element, called an index, is written in brackets following an array name. Array indices must be either numbers or strings.

Array elements can be of any data type. The elements in an array do not all need to be of the same type, and there is no limit to the number of elements an array may have.

The following statements demonstrate assigning values to arrays.

```
var array = new Array();
array[0] = "fish";
array[1] = "fowl";
array["joe"] = new Rectangle(3,4);
array[foo] = "creeping things"
array[goo + 1] = "etc."
```

The variables foo and goo must be either numbers or strings.

Since arrays use a number to identify the data they contain, they provide an easy way to work with sequential data. For example, suppose you wanted to keep track of how many jellybeans you ate each day, so you can graph your jellybean consumption at the end of the month. Arrays provide an ideal solution for storing such data.

```
var April = new Array();
April[1] = 233;
April[2] = 344;
April[3] = 155;
April[4] = 32;
```

Now you have all your data stored conveniently in one variable. You can find out how many jellybeans you ate on day x by checking the value of April[x]:

```
for(var x = 1; x < 32; x++)
    Screen.write("On April " + x + " I ate " + April[x] +
        " jellybeans.\n");
```

Arrays usually start at index [0], not index [1]. Note that arrays do not have to be continuous, that is, you can have an array with elements at indices 0 and 2 but none at 1.

SEE: [array.jsh - arrays and objects](#)

## Creating arrays

Like other objects, arrays are created using the `new` operator and the `Array` constructor function. There are three possible ways to use this function to create an array. The simplest is to call the function with no parameters:

```
var a = new Array();
```

This line initializes variable `a` as an array with no elements. The parentheses are optional when creating a new array, if there are no arguments. If you wish to create an array of a predefined size, pass variable `a` the size as a parameter of the `Array()` function. The following line creates an array with a length of the size passed.

```
var b = new Array(31);
```

In this case, an array with length 31 is created.

Finally, you can pass a list of elements to the `Array()` function, which creates an array containing all of the parameters passed. For example:

```
var c = new Array(5, 4, 3, 2, 1, "blast off");
```

creates an array with a length of 6. `c[0]` is set to 5, `c[1]` is set to 4, and so on up to `c[5]`, which is set to the string "blast off". Note that the first element of the array is `array[0]`, not `array[1]`.

Arrays may also be created dynamically. By referring to a variable with an index in brackets, a variable is created as or converted to an array. The array that is created is an automatic or dynamic array which is different than an instance of an **Array object** created as described in this section. Automatic arrays, created as described in this paragraph, are unable to use the methods and properties described below, so it is recommended that you use, in most circumstances, the `new Array()` constructor function to create arrays.

### Initializers for arrays and objects

Variables may be initialized as objects and arrays using lists inside of `"{}"` and `"[]"`. By using these initializers, instances of Objects and Arrays may be created without using the `new` constructor. Objects may be initialized using syntax similar to the following:

```
var o = {a:1, b:2, c:3};
```

This line creates a new object with the properties `a`, `b`, and `c` set to the values shown. The properties may be used with normal object syntax, for example, `o.a == 1`.

Arrays may be initialized using syntax similar to the following:

```
var a = [1, 2, 3];
```

This line creates a new array with three elements set to 1, 2, and 3. The elements may be used with normal array syntax, for example, `a[0] == 1`.

The distinction between Object and Array initializer might be a bit confusing when using a line with syntax similar to the following:

```
var a = {1, 2, 3};
```

This line also creates a new array with three elements set to 1, 2, and 3. The line differs from the first line, Object initializer, in that there are no property identifiers and differs from the second line, Array initializer, in that it uses "{}" instead of "[]". In fact, the second and third lines produce the same results. The elements may be used with normal array syntax, for example, `a[0] == 1`.

The following code fragment shows the differences.

```
var o = {a:1, b:2, c:3};
Screen.writeln(typeof o + " | " + o._class + " | " + o);

var a = [1, 2, 3];
Screen.writeln(typeof a + " | " + a._class + " | " + a);

var a= {1, 2, 3};
Screen.writeln(typeof a + " | " + a._class + " | " + a);
```

The display from this code is:

```
object | Object | [object Object]
object | Array | 1,2,3
object | Array | 1,2,3
```

As shown in the first display line, the variable `o` is created and initialized as an Object. The second and third lines both initialize the variable `a` as an Array. Notice that in all cases the `typeof` of the variable is `object`, but the class, which corresponds to the particular object and which is reflected in the `_class` property, shows which specific object is created and initialized.

## Array object instance properties

### Array length

---

SYNTAX: `array.length`

DESCRIPTION: The length property returns one more than the largest index of the array. Note that this value does not necessarily represent the actual number of elements in an array, since elements do not have to be contiguous.

By changing the value of the length property, you can remove array elements. For example, if you change `ant.length` to 2, `ant` will only have the first two members, and the values stored at the other indices will be lost. If we set `bee.length` to 2, then `bee` will consist of two members: `bee[0]`, with a value of 88, and `bee[1]`, with an undefined value.

SEE: [Array\(\)](#), [global.getArrayLength\(\)](#), [global.setArrayLength\(\)](#)

EXAMPLE: `// Suppose we had two arrays "ant" and "bee",`  
`// with the following elements:`

```
var ant = new Array();
ant[0] = 3;
ant[1] = 4;
ant[2] = 5;
ant[3] = 6;
```

```
var bee = new Array();
```

---

---

```
bee[0] = 88;
bee[3] = 99;

// The length property of both ant and bee
// is equal to 4, even though ant has twice
// as many actual elements as bee does.
```

---

## Array object instance methods

### Array()

---

**SYNTAX:** `new Array(length)`  
`new Array([element1, ...])`

**WHERE:** `length` - If this is a number, then it is the length of the array to be created. Otherwise, it is the element of a single-element array to be created.

`elementN` - list of elements to be in the new Array object being created.

**RETURN:** `object` - an **Array object** of the length specified or an Array object with the elements specified.

**DESCRIPTION:** The array returned from this function is an empty array whose length is equal to the `length` parameter. If `length` is not a number, then the length of the new array is set to 1, and the first element is set to the `length` parameter. Note that this can also be called as a function, without the `new` operator.

The alternate form of the Array constructor initializes the elements of the new array with the arguments passed to the function. The arguments are inserted in order into the array, starting with element 0. The length of the new array is set to the total number of arguments. If no arguments are supplied, then an empty array of length 0 is created.

**SEE:** [Automatic array allocation](#)

**EXAMPLE:**

```
var a = new Array(5);
var a = new Array(1, "two", three);
```

---

### Array concat()

---

**SYNTAX:** `array.concat([element1, ...])`

**WHERE:** `elementN` - list of elements to be concatenated to this Array object.

**RETURN:** `object` - a new array consisting of the elements of the current object, with any additional arguments appended.

**DESCRIPTION:** The return array is first constructed to consist of the elements of the current object. If the current object is not an **Array object**, then the object is converted to a string and inserted as the first element of the newly created array. This method then cycles through all of the arguments, and if they are arrays then the elements of the array are appended to the end of the return array, including empty elements. If an argument is not an array, then it is first converted to a string and appended as the last element of

---

---

the array. The length of the newly created array is adjusted to reflect the new length. Note that the original object remains unaltered.

SEE: [String concat\(\)](#)

EXAMPLE: 

```
var a = new Array(1,2);
var b = a.concat(3);
```

---

## Array join()

---

SYNTAX: `array.join([separator])`

WHERE: `separator` - a value to be converted to a string and used to separate the list of array elements. The default is an empty string.

RETURN: string - string consisting of the elements, delimited by separator, of an array.

DESCRIPTION: The elements of the current object, from 0 to the length of the object, are sequentially converted to strings and appended to the return string. In between each element, the separator is added. If `separator` is not supplied, then the single-character string "," is used. The string conversion is the standard conversion, except the undefined and null elements are converted to the empty string "".

The `Array join()` method creates a string of all of array elements. The `join()` method has an optional parameter, a string which represents the character or characters that will separate the array elements. By default, the array elements will be separated by a comma. For example:

```
var a = new Array(3, 5, 6, 3);
var string = a.join();
```

will set the value of "string" to "3,5,6,3". You can use another string to separate the array elements by passing it as an optional parameter to the `join()` method. For example,

```
var a = new Array(3, 5, 6, 3);
var string = a.join("*/");
```

creates the string "3\*/5\*/6\*/3".

SEE: [Array toString\(\)](#)

EXAMPLE: 

```
// The following code:
```

```
var array = new Array( "one", 2, 3, undefined );
Screen.writeln( array.join("::") );
```

```
// Will print out the string "one::2::3::".
```

---

## Array pop()

---

SYNTAX: `array.pop()`

RETURN: value - the last element of the current **Array object**. The element is removed from the array after being returned.

---

---

**DESCRIPTION:** This method first gets the length of the current object. If the length is undefined or 0, then undefined is returned. Otherwise, the element at this index is returned. This element is then deleted, and the length of current object is decreased by one. The `pop()` method works on the end of an array, whereas, the [Array shift\(\)](#) method works on the beginning.

**SEE:** [Array push\(\)](#)

**EXAMPLE:**

```
// The following code:

var array = new Array( "four" );
Screen.writeln( array.pop() );
Screen.writeln( array.pop() );

// Will first print out the string "four", and
// then print out "undefined",
// which is the result of converting
// the undefined value to a string.
// The array will be empty after these calls.
```

---

## **Array push()**

---

**SYNTAX:** `array.push([element1, ...])`

**WHERE:** `elementN` - a list of elements to append to the end of an array.

**RETURN:** number - the length of the new array.

**DESCRIPTION:** This method appends the arguments to the end of this array, in the order that they appear. The length of the current [Array object](#) is adjusted to reflect the change.

**SEE:** [Array pop\(\)](#)

**EXAMPLE:**

```
// The following code:

var array = new Array( 1, 2 );
array.push( 3, 4 );
Screen.writeln( array );

// Will print the array converted
// to the string "1,2,3,4".
```

---

## **Array reverse()**

---

**SYNTAX:** `array.reverse()`

**RETURN:** object - a new array consisting of the elements in the current [Array object](#) in reverse order.

**DESCRIPTION:** If the length of the current [Array object](#) is 0, then the current [Array object](#) is simply returned. Otherwise, a new [Array object](#) is created, and the elements of the current [Array object](#) are put into this new array in reverse order, preserving any empty or undefined elements.

**EXAMPLE:**

```
var a = new Array(1,2,3);
var b = a.reverse();

// The following code:
var array = new Array;
array[0] = "ant";
```

---

---

```
array[1] = "bee";
array[2] = "wasp";
array.reverse();

//produces the following array:

array[0] == "wasp"
array[1] == "bee"
array[2] == "ant"
```

---

## Array shift()

---

**SYNTAX:** `array.shift()`

**RETURN:** value - the first element of the current Array object. The element is removed from the array after being returned.

**DESCRIPTION:** If the length of the current **Array object** is 0, then `undefined` is returned. Otherwise, the first element is returned. This element is deleted from the array, and any remaining elements are shifted down to fill the gap that was created. The `shift()` method works on the beginning of an array, whereas, the **Array pop()** method works on the end.

**SEE:** [Array unshift\(\)](#), [Array pop\(\)](#)

**EXAMPLE:** `//The following code:`

```
var array = new Array( 1, 2, 3 );
Screen.writeln( array.shift() );
Screen.writeln( array );

// First prints out "1",
// and then the contents of the array,
// which converts to the string "2,3".
```

---

## Array slice()

---

**SYNTAX:** `array.slice(start[, end])`

**WHERE:** `start` - the element offset to start from.

`end` - the element offset to end at.

**RETURN:** object - a new array containing the elements of the current object from `start` up to, but not including, element `end`.

**DESCRIPTION:** This method creates a subset of the current array. If `end` is not supplied, then the length of the current object is used instead. If either `start` or `end` is negative, then it is treated as an offset from the end of the array, and the value `length+start` or `length+end` is used instead. If either is beyond the length of the array, then the length is used instead. If either is less than 0 after adjusting for negative values, then the value 0 is used instead. The elements are then copied into the newly created array, starting at `start` and proceeding to (but not including) `end`.

**SEE:** [String substring\(\)](#)

**EXAMPLE:** `// The following code:`

---

---

```
var array = new Array( 1, 2, 3, 4 );
Screen.writeln( array.slice( 1, -1 ) );

// Print out the elements from 1 up to 4,
// which results in the string "2,3".
```

---

## Array sort()

---

**SYNTAX:** `array.sort([compareFunction])`  
**WHERE:** `compareFunction` - identifier for a function which expects two parameters `x` and `y`, and returns a negative value if `x < y`, zero if `x = y`, or a positive value if `x > y`.

**RETURN:** object - this **Array object** after being sorted.

**DESCRIPTION:** This method sorts the elements of the array. The sort is not necessarily stable (that is, elements which compare equal do not necessarily remain in their original order). The comparison of elements is done based on the supplied `compareFunction`. If `compareFunction` is not supplied, then the elements are converted to strings and compared. Non-existent elements are always greater than any other element, and consequently are sorted to the end of the array. Undefined values are also always greater than any defined element, and appear at the end of the Array before any empty values. Once these two tests are performed, then the appropriate comparison is done.

If a compare function is supplied, the array elements are sorted according to the return value of the compare function. If `a` and `b` are two elements being compared, then:

- If `compareFunction(a, b)` is less than zero, sort `b` to a lower index than `a`.
- If `compareFunction(a, b)` returns zero, leave `a` and `b` unchanged relative to each other.
- If `compareFunction(a, b)` is greater than zero, sort `b` to a higher index than `a`.

By specifying the following function as a sort function, you will get the desired result when comparing numbers:

```
function compareNumbers(a, b)
{
    return a - b
}
```

**SEE:** [Clib strcmp\(\)](#)

**EXAMPLE:** `// Consider the following code,`  
`// which sorts based on numerical values,`  
`// rather than the default string comparison.`

```
function compare( x, y )
{
    x = ToNumber(x);
    y = ToNumber(y);

    if( x < y )
```

---

---

```

        return -1;
    else if ( x == y )
        return 0;
    else
        return 1;
}

var array = new Array( 3, undefined, "4", -1 );
array.sort(compare);
Screen.writeln(array);

// Prints out the sorted array,
// which is "-1,3,4,, ".
// Notice the undefined value
// at the end of the array.

```

---

## Array splice()

---

**SYNTAX:** `array.splice(start, deleteCount[, element1, ...])`

**WHERE:** `start` - the index at which to splice in the items. If this is negative, then `(length+start)` is used instead, and if it beyond the end of the array, then the length of the array is used.

`deletecount` - the number of items to remove from the array.

`elementN` - a list of elements to insert into the array in place of the ones which were deleted.

**RETURN:** object - an array consisting of the elements which were removed from the current **Array object**.

**DESCRIPTION:** This method splices in any supplied elements in place of any elements deleted. Beginning at index `start`, `deleteCount` elements are first deleted from the array and inserted into the newly created return array in the same order. The elements of the current object are then adjusted to make room for the all of the items passed to this method. The remaining arguments are then inserted sequentially in the space created in the current object.

**SEE:** [Array push\(\)](#)

**EXAMPLE:** `// The following code:`

```

var array = new Array( 1, 2, 3, 4, 5 );
Screen.writeln( array.splice( 1, 2, 6, 7, 8 ) );
Screen.writeln( array );

// Will print "2,3" and then "1,6,7,8,4,5"
// The array has been modified to include
// the extra items in place of those
// that were deleted.

```

---

## Array toString()

---

**SYNTAX:** `array.toString()`

**RETURN:** string - string representation of an **Array object**.

**DESCRIPTION:** This method behaves exactly the same as if **Array join()** was called on the current object with no arguments. The result is a

---

---

string consisting of the string representation of the array elements (except for null and undefined, which are empty strings) separated by commas.

SEE: [Array join\(\)](#)

EXAMPLE: 

```
// The following code:

var array = new Array( 1, "two", , null, false );
Screen.writeln( array.toString() );

// Will print out the string "1,two,,,false".
// Note that this method is rarely called,
// rather the function ToString() is used,
// which implicitly calls this method.
```

---

### **Array unshift()**

---

SYNTAX: `array.unshift([element1, ...])`

WHERE: `elementN` - a list of items to insert at the beginning of the array.

RETURN: number - the length of the new array after inserting the items.

DESCRIPTION: Any arguments are inserted at the beginning of the array, such that their order within the array is the same as the order in which they appear in the argument list. Note that this method is the opposite of [Array push\(\)](#), which adds the items to the end of the array.

SEE: [Array shift\(\)](#), [Array push\(\)](#)

EXAMPLE: 

```
var a = new Array(2,3);
var b = a.unshift(1);
```

---

---

# Blob Object

This section describes Blobs, Binary Large Objects.

The methods in this section are preceded with the object name Blob, since individual instances of the Blob object are not created. For example, `Blob.get()` is the syntax to use to get data from a Blob. Blob and Buffer variables overlap. The Buffer is the newer construct, and the Blob is retained mostly for compatibility with previous versions of ScriptEase. When necessary to work with data in memory, use a Buffer object if possible.

SEE: [Buffer object](#), Win32 structure definitions

## Blob object static methods

### Blob.get()

---

SYNTAX: `Blob.get(BlobVar, offset, DataType)`  
`Blob.get(BlobVar, offset, bufferLen)`  
`Blob.get(BlobVar, offset, DataStructureDefinition)`

WHERE: BlobVar - binary large object variable to use.

offset - the offset or position in the Blob from which to work.

DataType - the type of data with which to work.

bufferLen - the length of data to work with as a buffer or byte array.

DataStructureDefinition - definition of a structure (object) variable.

RETURN: value - the data retrieved according to the defining parameters.

DESCRIPTION: This method reads data from a specified location of a Binary Large Object, a Blob and is the companion function to [Blob.put\(\)](#). The parameter BlobVar specifies the Blob to use. The parameter offset specifies where, in the Blob, to get data. The last parameter specifies the format of the data in the Blob and, hence, determines the type of the value returned which is the data read from the Blob.

Valid values for DataType are:

`UWORD8, SWORD8, UWORD16, SWORD16, UWORD24, SWORD24, UWORD32, SWORD32, FLOAT32, FLOAT64, FLOAT80`

See [Clib.fread\(\)](#) or [blobDescriptor object](#), below, for more information on these DataType values.

SEE: [Blob put\(\)](#), [Blob size\(\)](#), [\\_BigEndianMode](#), [Buffer object](#)

---

### Blob.put()

---

SYNTAX: `Blob.put(BlobVar[, offset], variable, DataType)`  
`Blob.put(BlobVar[, offset], buffer, bufferLen)`  
`Blob.put(BlobVar[, offset], SrcStruct,`

---

---

WHERE:	<p><code>DataStructureDefinition</code>)</p> <p><code>BlobVar</code> - binary large object variable to use.</p> <p>offset - the offset or position in the Blob from which to work.</p> <p>variable - variable with data to put into a Blob.</p> <p>buffer - buffer with data to put into a Blob.</p> <p><code>SrcStruct</code> - structure (object) with data to put into a Blob.</p> <p><code>DataType</code> - the type of data with which to work.</p> <p>bufferLen - the length of data to work with as a buffer or byte array.</p> <p><code>DataStructureDefinition</code> - definition of an object (structure) variable.</p>
RETURN:	<p>number - the byte offset to the next byte following the data that was just inserted into a Blob. If at the end of a Blob, then return the value that equals <code>Blob.size(Blob)</code>.</p>
DESCRIPTION:	<p>This method puts data into a specified location of a Binary Large Object, Blob and, along with <code>Blob.get()</code>, allows for direct access to memory within a variable. The contents of such a variable may be viewed as a packed structure. Data can be placed at any location within a Blob. The parameter <code>BlobVar</code> specifies the Blob to use. The parameter <code>offset</code> specifies where, in the Blob, to write data. The third parameter is the data to write. The last parameter specifies the format of the data in the Blob.</p> <p><code>Blob.put()</code> returns the byte offset for the next byte following the section where data was just put. If the data is put at the end of the Blob, then the return is equivalent to the size of the Blob.</p> <p>If <code>offset</code> is not supplied, then the data is put at the end of the Blob, or at offset 0 if the Blob is not yet defined.</p> <p>The data in <code>v</code> is converted to the specified <code>DataType</code> and then copied into the bytes specified by <code>offset</code>.</p> <p>If <code>DataType</code> is not the length of a byte buffer, then it must be one of these types:</p> <p><code>UWORD8, SWORD8, UWORD16, SWORD16, UWORD24, SWORD24, UWORD32, SWORD32, FLOAT32, FLOAT64, FLOAT80</code></p> <p>See <code>Clib.fread()</code> or <code>blobDescriptor</code> object, below, for more information on these <code>DataType</code> values.</p>
SEE:	<p><a href="#">Blob get()</a>, <a href="#">Blob size()</a>, <a href="#">_BigEndianMode</a>, <a href="#">Buffer object</a></p>
EXAMPLE:	<pre>// If you were sending a pointer to data // in an external C library and knew // that the library expected the data // in a packed DOS structure of the form:  struct foo {     signed char a;</pre>

---

---

```

        unsigned int b;
        double      c;
    };

    // and if you were building this structure
    // from three corresponding variables,
    // then such a building function might look
    // like the following:

    function BuildFooBlob(a, b, c)
    {
        var offset = Blob.put(foo, 0, a, SWORD8);
        offset = Blob.put(foo, offset, b, UWORD16);
        Blob.put(foo, offset, c, FLOAT64);
        return foo;
    }

    // or, if an offset were not supplied:

    BuildFooBlob(a, b, c)
    {
        Blob.put(foo, a, SWORD8);
        Blob.put(foo, b, UWORD16);
        Blob.put(foo, c, FLOAT64);
        return foo;
    }

```

---

## **Blob.size()**

---

**SYNTAX:** `Blob.size(BlobVar[, SetSize])`  
`Blob.size(DataType)`  
`Blob.size(bufferLen)`  
`Blob.size(DataStructureDefinition)`

**WHERE:** `BlobVar` - binary large object variable to use.

`SetSize` - size to which to set `BlobVar`.

`DataType` - the type of data with which to work.

`bufferLen` - the length of data to work with as a buffer or byte array.

`DataStructureDefinition` - definition of a structure (object) variable.

**RETURN:** number - bytes in a `Blob` variable. If `SetSize` is passed, then that value is returned.

**DESCRIPTION:** This method determines the size of a Binary Large Object, `Blob`. The parameter `BlobVar` specifies the `Blob` to use. If `SetSize` is provided, then the `Blob` `BlobVar` is altered to this size or created with this size.

If `DataType`, `bufferLen`, or `DataStructureDefinition` are used, `Blob.size()` returns the size of a `Blob` that would contain the type of data item used in by `Blob.get()` or `Blob.put()`. In these cases, these parameters specify the type to be used for converting ScriptEase data to and from a `Blob`.

`Blob.size` returns the size of a `Blob`, which is the number of bytes in `BlobVar`. If `SetSize` is supplied, then the return is `SetSize`.

---

## blobDescriptor object

When an object (structure) needs to be sent to a process other than the ScriptEase interpreter, such as to a Windows API function, a `blobDescriptor` object must be created that describes the order and type of data in the object to be sent. This description tells how the properties of the object are stored in memory and used with functions such as `Clib.fread()` and `SElib.dynamicLink()`.

A `blobDescriptor` has the same data properties as the object it describes. Each property must be assigned a value that specifies how much memory is required for the data held by that property. Consider the following object.

```
Rectangle(width, height)
{
    this.width = width;
    this.height = height;
}
```

The following code creates a `blobDescriptor` object that describes the `Rectangle` object defined above:

```
var bd = new blobDescriptor();

bd.width = UWORD32;
bd.height = UWORD32;
```

You can now pass `bd` as a `blobDescriptor` parameter to functions, (such as `SElib.dynamicLink()`, `Clib.fread()`, and `Clib.fwrite()`), which might require one. The values assigned to the properties depend on what the receiving function expects. In the example above, the function that is called expects to receive an object that contains two 32-bit words or data values. If you write a `blobDescriptor` for a function that expects to receive an object containing two 16-bit words, assign the two properties a value of `UWORD16`.

The following values may be used for `blobDescriptors`.

<code>UWORD8</code>	Stored as a byte
<code>SWORD8</code>	Stored as an integer
<code>UWORD16</code>	Stored as an integer
<code>SWORD16</code>	Stored as an integer
<code>UWORD24</code>	Stored as an integer
<code>SWORD24</code>	Stored as an integer
<code>UWORD32</code>	Stored as an integer
<code>SWORD32</code>	Stored as an integer
<code>FLOAT32</code>	Stored as a float
<code>FLOAT64</code>	Stored as a float
<code>FLOAT80</code>	Stored as a float (not available in Win32)

If a `blobDescriptor` describes an object property that is a string, the corresponding property should be assigned a numeric value that is larger than the length of the longest string the property may hold. Object methods usually may be omitted from a `blobDescriptor`.

See Win32 structure definitions.

### blobDescriptor example

The Win32 API function *GetOpenFileName* is being used for this example. The syntax, in the Win32 API documentation, for this function is:

```
BOOL GetOpenFileName(LPOPENFILENAME lpofn);
```

The ScriptEase syntax for calling the Win32 API is:

```
SElib.dynamicLink(library, procedure, convention  
[, [desc,] param ...])
```

The first three parameters in the ScriptEase syntax are standard for all calls to the Win32 API and are not discussed here. See [SElib.dynamicLink\(\) - for Win32](#) for a complete discussion. In the current section, we are only dealing a structure parameter since the *lpofn* parameter in the *GetOpenFileName* API function is a pointer to a structure. Other parameters, not discussed here, such as, integers and double words, are handled in a straightforward way.

An actual call to the *GetOpenFileName* function might look like the following:

```
var rtn;  
rtn = SElib.dynamicLink("COMDLG32", "GetOpenFileNameA", STDCALL,  
ofnDesc, ofn);
```

We are concerned with the parameters: *ofnDesc* and *ofn*. The original function only required one parameter, *lpofn*, but we are passing two parameters. (Remember that the first three parameters: *library*, *procedure*, and *convention*, are parameters for *SElib.dynamicLink* and that the parameters to API functions begin after the first three.) Why two parameters? Because *ofn* is a structure and ScriptEase requires a description of the structure. Hence, *ofnDesc* is a **blobDescriptor object** and *ofn* is a structure, and, in ScriptEase, a structure is considered a binary large object.

Lets look at the *OpenFileName* structure that is defined in the Win32 API and required by the *GetOpenFileName* function. The structure is defined as:

```
typedef struct tagOFN { // ofn  
    DWORD        lStructSize;  
    HWND         hwndOwner;  
    HINSTANCE    hInstance;  
    LPCTSTR      lpstrFilter;  
    LPTSTR       lpstrCustomFilter;  
    DWORD        nMaxCustFilter;  
    DWORD        nFilterIndex;  
    LPTSTR       lpstrFile;  
    DWORD        nMaxFile;  
    LPTSTR       lpstrFileTitle;  
    DWORD        nMaxFileTitle;  
    LPCTSTR      lpstrInitialDir;  
    LPCTSTR      lpstrTitle;  
    DWORD        Flags;  
    WORD         nFileOffset;  
    WORD         nFileExtension;  
    LPCTSTR      lpstrDefExt;  
    DWORD        lCustData;  
    LPOFNHOOKPROC lpfnHook;
```

```

        LPCTSTR        lpTemplateName;
    } OPENFILENAME;

```

In ScriptEase, the `blobDescriptor` for the `OpenFileName` structure above could look like the following:

```

var ofnDesc = new blobDescriptor();

ofnDesc.lStructSize      = UWORD32;
ofnDesc.hwndOwner       = UWORD32;
ofnDesc.hInstance       = UWORD32;
ofnDesc.lpstrFilter     = UWORD32;
ofnDesc.lpstrCustomFilter = UWORD32;
ofnDesc.nMaxCustFilter  = UWORD32;
ofnDesc.nFilterIndex    = UWORD32;
ofnDesc.lpstrFile       = UWORD32;
ofnDesc.nMaxFile        = UWORD32;
ofnDesc.lpstrFileTitle  = UWORD32;
ofnDesc.nMaxFileTitle   = UWORD32;
ofnDesc.lpstrInitialDir = UWORD32;
ofnDesc.lpstrTitle      = UWORD32;
ofnDesc.Flags           = UWORD32;
ofnDesc.nFileOffset     = UWORD16;
ofnDesc.nFileExtension = UWORD16;
ofnDesc.lpstrDefExt     = UWORD32;
ofnDesc.lCustData       = UWORD32;
ofnDesc.lpfHook         = UWORD32;
ofnDesc.lpTemplateName = UWORD32;

```

As you can see, the ScriptEase `blobDescriptor` functions like a structure definition in another language and, specifically, like `struct` in C. The `OpenFileName` shown above is used with `typedef` for a `struct`, which might be a more useful comparison than just a structure definition. In any case, the similarity between structures and `blobDescriptors` is evident. Each property of the `blobDescriptor` object describes or determines how much memory is used by an element of a structure. For example, the first element of the Win32 API `OpenFileName` structure is `lStructSize` of type `DWORD`. In ScriptEase, the corresponding first property in `ofnDesc` is `lStructSize` and is defined as `UWORD32`. Both `DWORD` in the Win32 API and `UWORD32` in ScriptEase designate 32 bits of memory to hold data. Thus, the memory requirements, for a structure, in the Win32 API and in ScriptEase are coordinated.

Notice that the original structure element name is `lStructSize` and the object property name `lStructSize` are the same. They did not need to be. The property names in a `blobDescriptor` object can be any names of your choosing. It is the size designations, such as, `UWORD32`, that are important. This `blobDescriptor` is the parameter `desc` in the syntax statement for `SElib.dynamicLink()`.

Now we need to define the parameter `param` that is described. (Remember, `desc` is required only if the following `param` is a structure.) In our current example, `ofn` is the structure that is passed as `param` following the `ofnDesc` which is passed as `desc`. How might `ofn` be built since ScriptEase no longer has structure data types? Objects may be used as structures with object properties being equivalent to structure elements. So the following lines of code could be used:

```

#include "comdlg32.jsh"

```

```

#define MAXFILESIZE 65

var ofn = new Object();
    // Size of the ofn structure
ofn.lStructSize = Blob.size(ofnDesc);

    // Handle of owner, a ScriptEase screen in this example
ofn.hwndOwner = Screen.handle();

    // Set a buffer to pass and receive a filespec
var fileSpec;
fileSpec = new Buffer(MAXFILESIZE);
fileSpec.putString(`c:\bat\*.bat`);
fileSpec = fileSpec.toString();
    // Actually pass a pointer to this buffer
ofn.lpstrFile = SELib.pointer(fileSpec);
    // Set the maxsize for a filespec to pass and received
ofn.nMaxFile = MAXFILESIZE - 1;

    // Do the API call and get the function return
var rtn;
rtn = SELib.dynamicLink("COMDLG32", "GetOpenFileNameA", STDCALL,
    ofnDesc, ofn);

```

This code fragment would create a common open file dialog in a directory `c:\bat` and would show files with extensions of `bat`. The last statement is the `SELib.dynamicLink()` call. The object/structure `ofn` is passed, corresponding to the `lpofn` parameter in the original Win32 API syntax. The `ofnDesc` `blobDescriptor` is passed to describe `ofn` to ScriptEase so that ScriptEase may communicate properly with the Win32 API.

Notice two things about the `ofn` object/structure.

- The property names match the properties in the `blobDescriptor` `ofnDesc` that describes the `ofn` object/structure.
- Not all of the properties of the `ofn` object/structure needed to be initialized to values. We created a simple open dialog that did not need any data except the properties/elements that we defined. Often, it is not necessary to define data elements that are passed to an API function, if the data is not used. Be careful though. If you are not sure about whether or not to initialize all elements, it is a safe practice to initialize them to default values specified by API documentation.

Another thing of interest in this code fragment is how it handles string data. The `lpstrFile` property/element is used to pass a string to and receive a string from the `GetOpenFileNameA` API function. The method shown here is one way, among other techniques to handle string data. The API `OpenFileName` structure requires a point to a string buffer, not the string itself. Therefore, this fragment creates a buffer `fileSpec` of the proper size. It then puts the string with a file specification into the buffer and then converts the buffer to a string. ScriptEase strings may contain `"\0"` characters. The `Buffer toString()` method creates a string of the same length as the buffer and includes all of the `"\0"` characters after the string ``c:\bat\*.bat``. Then the element `lpstrFile` is assigned a pointer to the string `fileSpec`, which started its existence as a `Buffer` object. The file name selected in the open dialog will be returned in the `fileSpec` string/buffer. We have been discussing the following lines:

```
var fileSpec;
fileSpec = new Buffer(MAXFILESIZE);
fileSpec.putString(`c:\bat\*.bat`);
fileSpec = fileSpec.toString();
    // Actually pass a pointer to this buffer
ofn.lpstrFile = SElib.pointer(fileSpec);
```

We could have accomplished the task of passing and receiving string data with the following lines (which are similar to the ones above):

```
var fileSpec;
fileSpec = new Buffer(MAXFILESIZE);
fileSpec.putString(`c:\bat\*.bat`);
    // Actually pass a pointer to this buffer
ofn.lpstrFile = SElib.pointer(fileSpec.data);
```

The main difference is that the string data is in a buffer when passed and returned. To work with the returned string data, the buffer must be converted to a string if you want to use string methods and functions with it.

---

# Boolean Object

## Boolean object instance methods

### Boolean()

---

SYNTAX:	<code>new Boolean(value)</code>
WHERE:	value - a value to be converted to a boolean.
RETURN:	object - a Boolean object with the parameter value converted to a boolean value.
DESCRIPTION:	This function creates a <b>Boolean object</b> that has the parameter value converted to a boolean value. If the function is called without the <code>new</code> constructor, then the return is simply the parameter value converted to a boolean.
SEE:	<a href="#">Boolean toString()</a>
EXAMPLE:	<pre>var name = "Joe"; var b = new Boolean( name == "Joe" ); // The Boolean object "b" is now true.</pre>

---

### Boolean.toString()

---

SYNTAX:	<code>boolean.toString()</code>
RETURN:	string - "true" or "false" according to the value of the Boolean object.
DESCRIPTION:	This <code>toString()</code> method returns a string corresponding to the value of a <b>Boolean object</b> or primitive data type.
SEE:	<a href="#">Boolean toString()</a> , <a href="#">boolean type</a>
EXAMPLE:	<pre>var name = "Joe"; var b = new Boolean( name === "Joe" ); var bb = false; Screen.writeln(b.toString()); // "true" Screen.writeln(bb.toString()); // "false"</pre>

---

---

# Buffer Object

The Buffer object provides a way to manipulate data at a very basic level. It is needed whenever the relative location of data in memory is important. Any type of data may be stored in a Buffer object. A new Buffer object may be created from scratch, from a string, another Buffer object, or from most any data type or object (see [global.ToBuffer\(\)](#)).

(See the helper file `buffer.jsh` for enhancements to the Buffer object.)

ScriptEase 5.00 introduced an important change in buffers. Prior to version 5.00 ScriptEase JavaScript had a buffer data type, as well as, a Buffer object. Beginning with ScriptEase 5.00, buffer data types no longer exist, only the Buffer object. The scripts distributed with ScriptEase Desktop have been updated to reflect the changes, but users might have some personal scripts that need changing. So, some key differences in working with buffers as objects only, without a unique data type, are discussed now.

First, many (probably most) script statements, using buffers, do need to be changed. All of the Buffer and Blob methods still work as they did before. The primary difference is in the use of the [Buffer\(\)](#) function without the `new` constructor, the use of the `data` property in a Buffer object, and the use of the `length` and `size` properties.

Previously, the `Buffer()` function returned a buffer data type and the `new Buffer()` constructor returned a Buffer object. The `data` property of the Buffer object could be used to access the actual buffer data in the object. The `length` property could be used with a buffer data type to get the length of a buffer. Now both `Buffer()` and `new Buffer()` return a Buffer object, and the `data` property no longer exists. Plus, only the `size` property may be used to get the size or length of a buffer. The following fragments illustrate these differences.

Prior to ScriptEase 5.00

```
var b1 = Buffer("abc");      // b1 is buffer data type
var b2 = new Buffer("abc");  // b2 is Buffer object
Screen.writeln(b1);        // abc
Screen.writeln(b1.data);    // abc
Screen.writeln(b1.length);  // 3
Screen.writeln(b2.length);  // 3
Screen.writeln(b2);        // abc
Screen.writeln(b2.data);    // abc
Screen.writeln(b1.size);    // 3
Screen.writeln(b2.size);    // 3
```

Starting with ScriptEase 5.00

```
var b1 = Buffer("abc");      // b1 is Buffer object
var b2 = new Buffer("abc");  // b2 is Buffer object
Screen.writeln(b1);        // abc
Screen.writeln(b1.data);    // undefined
Screen.writeln(b1.length);  // undefined
Screen.writeln(b2.length);  // undefined
Screen.writeln(b2);        // abc
Screen.writeln(b2.data);    // undefined
Screen.writeln(b1.size);    // 3
Screen.writeln(b2.size);    // 3
```

Most ScriptEase functions and methods are now smart enough to handle Buffer objects as they once did buffer data types, but small changes might be needed in some places. For example, previously, some `SElib.dynamicLink()` calls required a buffer data type. But now a Buffer object may be used. So if you have code (prior to ScriptEase 5.00) like:

```
var buf = Buffer(256); // creates a buffer data type
SElib.dynamicLink("user32", "GetClassNameA", STDCALL,
                 this.handle, buf, buf.length);
this.className = buf.getString();
return this.className;
```

With code starting after ScriptEase 5.00, the fragment above should work with the one correction, **length** to **size**, as shown in bold.

```
var buf = Buffer(256); // creates a Buffer object
SElib.dynamicLink("user32", "GetClassNameA", STDCALL,
                 this.handle, buf, buf.size);
this.className = buf.getString();
return this.className;
```

The example above is taken from the `Window.prototype.getClassName()` instance method definition in *winobj.js*. To illustrate changes due to the use of the data property, we take our example from the `Window.prototype.getClientRect()` instance method defined in *winobj.js*. Prior to ScriptEase 5.00 it was defined as:

```
var rtn;
var Rect = new Buffer(4+4+4+4); // hold 4 integers of 4 bytes

if (rtn = SElib.dynamicLink("user32", "GetClientRect", STDCALL,
                           this.handle, Rect.data))
{
    this.client.left    = Rect.getValue(4);
    this.client.top     = Rect.getValue(4);
    this.client.right   = Rect.getValue(4);
    this.client.bottom  = Rect.getValue(4);
}
```

In ScriptEase 5.00 it needs to be corrected in one place: the removal of the data property.

```
return rtn != NULL;

var rtn;
var Rect = new Buffer(4+4+4+4); // hold 4 integers of 4 bytes

if (rtn = SElib.dynamicLink("user32", "GetClientRect", STDCALL,
                           this.handle, Rect))
{
    this.client.left    = Rect.getValue(4);
    this.client.top     = Rect.getValue(4);
    this.client.right   = Rect.getValue(4);
    this.client.bottom  = Rect.getValue(4);
}

return rtn != NULL;
```

SEE: [Blob object](#)

## Buffer object instance properties

### Buffer bigEndian

---

SYNTAX: `buffer.bigEndian`

DESCRIPTION: This property is a boolean flag specifying whether to use bigEndian byte ordering when calling [Buffer getValue\(\)](#) and [Buffer putValue\(\)](#). This value is set when a buffer is created, but may be changed at any time. This property defaults to the state of the underlying OS and processor.

SEE: [Buffer unicode](#), [Buffer\(\)](#)

EXAMPLE:

```
/******  
The default behavior for a Windows 2000  
using an i386 type of processor results  
in the following buffer or 6 bytes:  
    65 00 66 00 67 00  
*****/  
var i;  
var b = new Buffer("ABC", true);  
  
/******  
With bigEndian set, as in the following,  
the buffer is:  
    00 65 00 66 00 67  
*****/  
var i;  
var b = new Buffer("ABC", true, true);
```

---

### Buffer cursor

---

SYNTAX: `buffer.cursor`

DESCRIPTION: The current position within a buffer. This value is always between 0 and `.size`. It can be assigned to as well. If a user attempts to move the cursor beyond the end of a buffer, then the buffer is extended to accommodate the new position, and filled with NULL, "\0", bytes. If a user attempts to set the cursor to less than 0, then it is set to the beginning of the buffer, to position 0.

SEE: [Buffer bigEndian](#), [Buffer size](#)

EXAMPLE:

```
var b = new Buffer("@ABCDE");  
// now b.cursor == 0  
b.cursor = 3;  
Screen.writeln(b.getValue()); // 67 - ASCII for "C"
```

---

### Buffer size

---

SYNTAX: `buffer.size`

DESCRIPTION: The size of the [Buffer object](#). This property may be assigned to, such as `foo.size = 5`. If a user changes the size of the buffer to something larger, then it is filled with NULL bytes. If the user sets the Buffer size to a value smaller than the

---

---

current position of the **Buffer cursor**, then the cursor is moved to the end of the new buffer.

SEE: [Buffer cursor](#)

EXAMPLE: 

```
var n = buffer.size;
```

---

## Buffer unicode

---

SYNTAX: `buffer.unicode`

DESCRIPTION: This property is a boolean flag specifying whether to use unicode strings when calling **Buffer getString()** and **Buffer putString()**. This value is set when the buffer is created, but may be changed at any time. This property defaults to the unicode status of the underlying ScriptEase engine.

When the **Buffer toString()** method is used with a Unicode buffer, an ASCII based string, of type `string`, is returned.

The size of an Unicode buffer is usually twice the size of an ASCII based, or byte based, buffer. For example,

```
var b1 = new Buffer("abc");  
var b2 = new Buffer("abc", true);
```

Result in the following:

```
b1.size == 3  
b2.size == 6;
```

SEE: [Buffer bigEndian](#), [Buffer\(\)](#)

EXAMPLE: 

```
var b1 = new Buffer("abc", true);  
// b1.unicode == true;
```

---

## Buffer[] Array

---

SYNTAX: `buffer[offset]`

RETURN: `number` - the value in a buffer at the index or `offset` specified. If a value is being assigned to this position, the value assigned is returned.

DESCRIPTION: This is an array- like version of the **Buffer getValue()** and **Buffer putValue()** methods, which works only with bytes. A user may either get or set these values, such as `goo = foo[5]` or `foo[5] = goo`. Every get/put operation uses byte types, that is, `SWORD8`. If `offset` is less than 0, then 0 is used. If `offset` is beyond the end of a buffer, the size of the buffer is extended with `NULL` bytes to accommodate it.

Every time an index value is used, the **Buffer cursor** property for an object is set to the next index, as with **Buffer putValue()** and **Buffer getValue()**.

SEE: [Buffer getValue\(\)](#), [Buffer putValue\(\)](#)

EXAMPLE: 

```
var b = new Buffer("ABC");  
// b.cursor == 0  
Screen.writeln(b[1]); // 66 - ASCII code for "B"
```

---

---

```
// now b.cursor == 2
b[0] = 68; // "DBC"
// now b.cursor == 1
```

---

## Buffer object instance methods

### Buffer()

---

SYNTAX: `new Buffer([size[, unicode[, bigEndian]])`  
`new Buffer(string[, unicode[, bigEndian]])`  
`new Buffer(buffer[, unicode[, bigEndian]])`  
`new Buffer(bufferObject)`

WHERE: `size` - size of buffer to be created.

`string` - string of characters from which to create a buffer.

`buffer` - buffer of characters from which to create another buffer.

`bufferObject` - buffer to be duplicated.

`unicode` - boolean flag for the initial state of the **Buffer unicode** property of this buffer.

`bigEndian` - numeric description of the initial state of the **Buffer bigEndian** property of this buffer.

RETURN: `object` - the new Buffer object created.

DESCRIPTION: To create a **Buffer object**, use syntax as shown by the following:

```
new Buffer([size[, unicode[, bigEndian]]];
```

A line of code following this syntax creates a new Buffer object. If `size` is specified, then the new buffer is created with the specified size, filled with `null` bytes. If no size is specified, then the buffer is created with a size of 0, though it can be extended dynamically later. The `unicode` parameter is an optional boolean flag describing the initial state of the `.unicode` flag of the object. Similarly, `bigEndian` describes the initial state of the `bigEndian` parameter of the buffer. If unspecified, these parameters default to the values described below.

```
new Buffer(string[, unicode[, bigEndian]]];
```

A line of code following this syntax creates a new Buffer object from the string provided. If `string` is a unicode string (`unicode` is enabled within the application), then the buffer is created as a unicode string. This behavior can be overridden by specifying `true` or `false` with the optional boolean `unicode` parameter. If this parameter is set to `false`, then the buffer is created as an ASCII string, regardless of whether or not the original string was in unicode or not. Similarly, specifying `true` will ensure that the buffer is created as a unicode string. The size of the buffer is the length of the string (twice the length if it is unicode). This constructor does not add a terminating `null` byte at the end of the string. The `bigEndian` flag behaves the same way as in the first constructor.

---

---

```
new Buffer(buffer[, unicode[, bigEndian]])
```

A line of code following this syntax creates a new Buffer object from the buffer provided. The contents of the buffer are copied as is into the new Buffer object. The unicode and bigEndian parameters do not affect this conversion, though they do set the relevant flags for future use.

```
new Buffer(bufferObject);
```

A line of code following this syntax creates a new Buffer object from another Buffer object. Everything is duplicated exactly from the other bufferObject, including the **Buffer cursor** location and the **Buffer size**.

All of the Buffer construction calls above may be done without the new constructor starting with ScriptEase 5.00.

SEE: [Blob object](#)

---

### **Buffer getString()**

---

SYNTAX: `buffer.getString([length])`

WHERE: `length` - number of characters to get from the buffer.

RETURN: string - starting from the current cursor location and continuing for length bytes. If no length is specified, then the method reads until a NULL byte is encountered or the end of the buffer is reached.

The **Buffer cursor** property is updated to the position after the string returned.

DESCRIPTION: The string is read according to the value of the .unicode flag of the buffer. A terminating NULL byte is not added, even if a length parameter is not provided.

SEE: [Buffer putString\(\)](#)

EXAMPLE: 

```
foo = new Buffer("abcd");
foo.cursor = 1;
goo = foo.getString(2);
//goo is now "bc"
```

---

### **Buffer compare()**

---

SYNTAX: `buffer.compare(buffer2)`

WHERE: `buffer2` - buffer to compare against.

RETURN: negative if `buffer < buffer2`,  
zero if `buffer == buffer2`  
positive if `buffer > buffer2`

DESCRIPTION: This function is identical to calling `Buffer.compare(buffer, buffer2)`.

SEE: [Buffer\(\)](#), [Buffer.compare\(\)](#), [Buffer.equal\(\)](#), [Buffer equal\(\)](#)

EXAMPLE: 

```
// The following code:
var bufa = Buffer("ab");
```

---

---

```
var bufb = new Buffer("ab\0");
var cmp = bufa.compare(bufb)
// will set the variable cmp to be < 0
```

---

### Buffer equal()

---

**SYNTAX:** `buffer.equal(buffer2)`  
**WHERE:** `buffer2` - buffer to compare against.

**RETURN:** true if two buffers are equal, else false

**DESCRIPTION:** This function is identical to calling `Buffer.equal(buffer,buffer2)`.

**SEE:** [Buffer\(\)](#), [Buffer equal\(\)](#), [Buffer.compare \(\)](#), [Buffer compare\(\)](#)

**EXAMPLE:**

```
// The following code:
var bufa = Buffer("ab");
var bufb = new Buffer("ab\0");
var cmp = bufa.equal(bufb)
// will set the variable cmp to be false
```

---

### Buffer getValue()

---

**SYNTAX:** `buffer.getValue([valueSize[, valueType]])`  
**WHERE:** `valueSize` - a positive number describing the number of bytes to be used and defaults to 1. The following are acceptable values: 1, 2, 3, 4, 8, and 10

`valueType` - One of the following types: "signed", "unsigned", or "float". The default type is "signed."

**RETURN:** number - from the position, specified by the `cursor` property, in a [Buffer object](#).

**DESCRIPTION:** This call is similar to the [Buffer putValue\(\)](#) function, except that it gets a value instead of puts a value.

**SEE:** [Buffer putValue\(\)](#), [Buffer\[\] Array](#)

**EXAMPLE:**

```
/*
To explicitly put a value at a specific location
while preserving the cursor location,
do something similar to the following.
*/

// Save the old cursor location
var oldCursor = foo.cursor;
// Set to new location
foo.cursor = 20;
// Get goo at offset 20
bar = foo.getValue(goo);
// Restore cursor location
foo.cursor = oldCursor

//Please see Buffer.putValue
// for a more complete description.
```

---

### Buffer putString()

---

**SYNTAX:** `buffer.putString(string)`  
**WHERE:** `string` - Any string.

---

---

RETURN: void.

DESCRIPTION: This method puts a string into the **Buffer object** at the current cursor position. If the `.unicode` flag is set within the Buffer object, then the string is put as a unicode string, otherwise it is put as an ASCII string. The cursor is incremented by the length of the string (or twice the length if it is put as a unicode string). Note that terminating null byte is not added at end of the string.

EXAMPLE: 

```
// To put a null terminated string,
// the following can be done.

    // Put the string into the buffer
foo.putString( "Hello" );
    // Add terminating null byte
foo.putValue( 0 );
```

---

### Buffer putValue()

---

SYNTAX: `buffer.putValue(value[, valueSize[, valueType]])`

WHERE: `value` - the value, a number, to be put into the buffer at the position indicated by the `cursor` property.

`valueSize` - a positive number describing the number of bytes to be used and defaults to 1. The following are acceptable values: 1,2,3,4,8, and 10

`valueType` - One of the following types: "signed", "unsigned", or "float". The default type is: "signed."

RETURN: void

The `value` is put into buffer at the current `cursor` position, and the cursor value is automatically incremented by the size of the value to reflect this addition.

DESCRIPTION: This method puts the specified `value` into a buffer. The value must be a number. The parameter `valueSize` or both `valueSize` and `valueType` may be passed as additional parameters. The parameter `valueSize` is a positive number describing the number of bytes to be used and defaults to 1. Acceptable values for `valueSize` are 1, 2, 3, 4, 8, and 10, providing that it does not conflict with the optional `valueType` flag. (See listing below.)

The parameter `valueType` must be one of the following:

"signed", "unsigned", or "float". It defaults to "signed."

The `valueType` parameter describes the type of data to be read.

Combined with `valueSize`, any type of data can be put. The following list describes the acceptable combinations of `valueSize` and `valueType`:

<code>valueSize</code>	<code>valueType</code>
1	signed, unsigned
2	signed, unsigned
3	signed, unsigned
4	signed, unsigned, float
8	float

---

Any other combination will cause an error. The value is put into buffer at the current cursor position, and the cursor value is automatically incremented by the size of the value to reflect this addition.

SEE: [Buffer getValue\(\)](#), [Buffer\[\] Array](#)

```
EXAMPLE:  /*
           To explicitly put a value at a specific location
           while preserving the cursor location,
           do something similar to the following.
           */

           var oldCursor = foo.cursor;
           // Save the old cursor location
           foo.cursor = 20;
           // Set to new location
           foo.putValue(goo);
           // Put goo at offset 20
           foo.cursor = oldCursor
           // Restore cursor location

           /*.
           The value is put into the buffer with byte-ordering
           according to the current setting of the .bigEndian
           flag. Note that when putting float values as a
           smaller size, such as 4, some significant figures
           are lost. A value such as "1.4" will actually be
           converted to something to the effect
           of "1.39999974". This is sufficiently
           insignificant to ignore, but note
           that the following does not hold true.
           .*/

           foo.putValue(1.4,4,"float");
           foo.cursor -= 4;
           if( foo.getValue(4,"float") != 1.4 )
               // This is not necessarily true due
               // to significant figure loss.

           /*.
           This situation can be prevented by using 8 or 10
           as a valueSize instead of 4. A valueSize of 4
           may still be used for floating point values,
           but be aware that some loss of significant figures
           may occur (though it may not be enough
           to affect most calculations).
           .*/
```

---

### Buffer subBuffer()

---

SYNTAX: `buffer.subBuffer(begin, end)`  
 WHERE: `begin` - start of offset  
       `end` - end of offset (up to but not including this point)  
 RETURN: object - another **Buffer object** consisting of the data between the  
       positions specified by the parameters: `begin` and `end`.  
 DESCRIPTION: If the parameter `begin` is less than 0, then it is treated as 0, the

---

---

start of the buffer. If the parameter `end` is beyond the end of the buffer, then the new sub-buffer is extended with `NULL` bytes. The original buffer is not altered.

SEE: [String subString\(\)](#)

EXAMPLE: 

```
foo = new Buffer("abcd");
bar = foo.subBuffer(1,3);
// bar is now the string "bc"
// "a" was at position 0, "b" at position 1, etc.
// The parameter "3"
// or "nEnd" is the position to go up to,
// but NOT to be included in the string.
```

---

### **Buffer toString()**

---

SYNTAX: `buffer.toString()`

RETURN: `string` - a string equivalent of the current state of the buffer, with all characters, including `"\0"`.

DESCRIPTION: Any conversion to or from unicode is done according to the `.unicode` flag of the object.

SEE: [Buffer getString\(\)](#)

EXAMPLE: 

```
foo = new Buffer("hello");
bar = foo.toString(void);
//bar is now the string "hello"
```

---

## **Buffer object static methods**

### **Buffer.compare ()**

---

SYNTAX: `Buffer.compare(buffer1,buffer2)`

WHERE: `buffer1,buffer2` - Two buffer objects to be compared.

RETURN: `negative` if `buffer1 < buffer2`,  
`zero` if `buffer1 == buffer2`  
`positive` if `buffer1 > buffer2`

DESCRIPTION: There is no insensitive compare, `Buffer.comparei()`, since buffers are not strings. To compare buffers as strings, use the `toString()` or `valueOf()` methods and make string comparisons. By using these methods, ASCII and Unicode buffers, holding string data, may be compared.

SEE: [Buffer\(\)](#), [Buffer compare\(\)](#), [Buffer.equal \(\)](#), [Buffer equal\(\)](#)

EXAMPLE: 

```
// The following code:
var bufa = Buffer("ab");
var bufb = new Buffer("ab\0");
var cmp = Buffer.compare(bufa,bufb)
// will set the variable cmp to be < 0
```

---

### **Buffer.equal ()**

---

SYNTAX: `Buffer.equal(buffer1,buffer2)`

WHERE: `buffer1,buffer2` - Two buffer objects to be compared.

RETURN: `true` if two buffers are equal, else `false`

DESCRIPTION: There is no insensitive compare, `Buffer.equali()`, since buffers are not strings. To compare buffers as strings, use the `toString()`

---

---

or `valueOf()` methods and make string comparisons. By using these methods, ASCII and Unicode buffers, holding string data, may be compared.

SEE: [Buffer\(\)](#), [Buffer equal\(\)](#), [Buffer.compare \(\)](#), [Buffer compare\(\)](#)

EXAMPLE: 

```
// The following code:
var bufa = Buffer("ab");
var bufb = new Buffer("ab\0");
var cmp = Buffer.equal(bufa,bufb)
// will set the variable cmp to be false
```

---

---

# Clib Object

platform: All operating systems; all versions of SE

The Clib object contains functions that are a part of the standard C library. Methods to access files, strings, and characters are all part of the Clib object.

Some of the functions in the Clib Object overlap the methods in JavaScript. In most cases, the newer JavaScript methods should be preferred over the older C functions. However, there are times, such as when working with routines that expect null terminated strings, that the Clib methods make more sense and are more consistent in a section of a script.

Clib functions with equivalent methods in JavaScript are noted as such. Since ScriptEase, JavaScript and the ECMAScript standard are developing and growing, generally, a programmer should favor the JavaScript methods over equivalent methods in the Clib object.

The methods in this section are preceded with the Object name Clib, since individual instances of the Clib Object are not created. For example, `Clib.exit()` is the syntax to use to exit a script.

## Console I/O functions

Console I/O functions are not available for ScriptEase WebServer Edition

### Clib.printf()

---

SYNTAX: `Clib.printf(formatString[, variables ...])`

WHERE: `formatString` - string that specifies the final format.

`variables` - values to be converted to and formatted as a string.

RETURN: `number` - characters written, or a negative number if there is an error.

DESCRIPTION: This method writes output to the standard output device according to the format string and returns a number equal to the number of characters written, or a negative number if there is an error. The format string can contain character combinations indicating how following parameters are to be treated. Characters are printed as read to standard output until a percent character, %, is reached. % indicates that a value is to be printed from the parameters following the format string. Each subsequent parameter specification takes from the next parameter in the list following format. A parameter specification has the following form in which square brackets indicate optional fields and angled brackets indicate required fields:

`%[flags][width][.precision]<type>`

flags may be:

- -  
Left justification in the field with blank padding; else right justifies with zero or blank padding
  - +
-

---

Force numbers to begin with a plus (+) or minus (-)

- blank  
Negative values begin with a minus (-); positive values begin with a blank
- #  
Convert using the following alternate form, depending on output data type:
  - c, s, d, i, u  
No effect
  - o  
0 (zero) is prepended to non- zero output
  - x, X  
0x, or 0X, are prepended to output
  - f, e, E  
Output includes decimal even if no digits follow decimal
  - g, G  
Same as e or E but trailing zeros are not removed

width may be:

- n  
(n is a number e.g., 14) At least n characters are output, padded with blanks
- 0n  
At least n characters are output, padded on the left with zeros
- \*  
The next value in the argument list is an integer specifying the output width
- .precision  
If precision is specified, then it must begin with a period (.), and may be as follows:
  - 0  
For floating point type, no decimal point is output
  - n  
n characters or n decimal places (floating point) are output
  - \*  
The next value in the argument list is an integer specifying the precision width

type may be:

- d, i  
signed integer
  - u  
unsigned integer
  - o  
octal integer x
  - x
-

---

hexadecimal integer with 0- 9 and a, b, c, d, e, f

- X  
hexadecimal integer with 0- 9 and A, B, C, D, E, F
- f  
floating point of the form [- ]dddd.dddd
- e  
floating point of the form [- ]d.ddde+dd or [- ]d.ddde- dd
- E  
floating point of the form [- ]d.dddE+dd or [- ]d.dddE- dd
- g  
floating point of f or e type, depending on precision
- G  
floating point of For E type, depending on precision
- c  
character (e.g. 'a', 'b', '8')
- s  
string

To include the % character as a character in the format string, you must use two % characters together, %% , to prevent the computer from trying to interpret it as one of the above forms.

SEE: [Clib.printf\(\)](#)

EXAMPLE: 

```
//Each of the following lines shows
// a printf example followed by what would show
// on the output in boldface:

Clib.printf("Hello world!")
// Hello world!
Clib.printf("I count: %d %d %d.",1,2,3)
// I count: 1 2 3
var a = 1;
var b = 2;
Clib.printf("%d %d %d", a, b, a +b)
// 1 2 3
```

---

## **Clib.getch()**

---

SYNTAX: `Clib.getch()`

RETURN: number - character value of the key pressed.

DESCRIPTION: This method works exactly like `getche()`, but does not echo the returned key to the screen. For example, the following code has you enter a password; each time you enter a letter an asterisk is written to the screen:

SEE: [Clib.getchar\(\)](#)

EXAMPLE: 

```
var password;
for (var gg = 0; ;gg++)
{
var letter = Clib.getch();
if (letter == '\n') continue;
Clib.putc('*').
password[gg] = letter;
}
```

---

---

## **Clib.getchar()**

---

SYNTAX: `Clib.getchar()`

RETURN: number - character value of the key pressed.

DESCRIPTION: This method returns the next character from stdin. Usually, this is the keyboard, but you may redefine it to something else. This method will wait for <Enter> to be pressed after the key, and will then return two values: the key pressed, and then the value of the enter key.

SEE: [Clib.getche\(\)](#)

---

---

## **Clib.getche()**

---

SYNTAX: `Clib.getche()`

RETURN: number - character value of the key pressed.

DESCRIPTION: This method waits until a key is pressed and returns the character value of that key. The character will be printed (echoed) to the screen. Some key presses, such as extended keys and function keys, may generate multiple `Clib.getche()` return values. If a key was pressed before calling the function but never cleared from the keyboard buffer, that value will be returned instead of the next pressed key. This is not a common occurrence but can happen. To see whether there are any key values pending in the keyboard buffer, use [Clib.kbhit\(\)](#).

SEE: [Clib.getch\(\)](#)

---

---

## **Clib.gets()**

---

SYNTAX: `Clib.gets(str)`

RETURN: str - buffer to hold the same string that is returned.

RETURN: string - an entire string from the keyboard, or `null` if there was an error.

DESCRIPTION: This method reads an entire string from the keyboard and returns it (or `null` if there was an error). The function will read all characters up to a newline character or EOF. If a newline character is read, it will not be included in the string.

SEE: [Clib.getchar\(\)](#)

EXAMPLE: `var s = Clib.gets()`

---

---

## **Clib.kbhit()**

---

SYNTAX: `Clib.kbhit()`

RETURN: boolean - `true` if there are any keystrokes waiting, `false` if not.

DESCRIPTION: This method checks to see whether there are any keystrokes waiting to be processed, returning `true` if there are and `false` if there are not.

---

---

SEE: [Clib.getche\(\)](#)

---

### **Clib.putchar()**

---

SYNTAX: `Clib.putchar(chr)`

WHERE: `chr` - character to write to the stream `stdout`.

RETURN: number - character written on success, else `EOF`.

DESCRIPTION: This method writes `chr` to the stream defined by `stdout` (usually the screen). If successful, it will return the character it just wrote; if not, it will return `EOF`.

This method is identical to `Clib.fputc(chr, stdout)`.

SEE: [Clib.puts\(\)](#), [Clib.fputc\(\)](#)

---

### **Clib.puts()**

---

SYNTAX: `Clib.puts(str)`

WHERE: `str` - string to write to the stream `stdout`.

RETURN: number - a positive number on success, else `EOF`.

DESCRIPTION: Writes a string to `stdout`, followed by a newline character. Will not write the final `null` character of `null` terminated strings. Returns `EOF` if there is an error writing the string; otherwise it returns a positive number.

This method is the same as `Clib.fputs(str, stdout)` except that a newline character is written after the string.

SEE: [Clib.putchar\(\)](#), [Clib.puts\(\)](#)

---

### **Clib.scanf()**

---

SYNTAX: `Clib.scanf(formatString, variables[, ...])`

WHERE: `formatString` - specifies how to read and store data in variables.

`variables` - list of variables to hold data input according to `formatString`.

RETURN: number - input items assigned.

DESCRIPTION: This flexible method reads input from the screen, extracts data from it by matching the string to a format string (as described below), and stores the data in the variables which follow the format string. It returns the number of input items assigned; this number may be fewer than the number of parameters requested if there was a matching failure. The format string contains character combinations that specify the type of data expected. The format string specifies the admissible input sequences, and how the input is to be converted to be assigned to the variable number of arguments passed to this function.

Characters are matched against the input as read and as it matches a portion of the format string until a `%` character is

---

---

reached. % indicates that a value is to be read and stored to subsequent parameters following the format string. Each subsequent parameter after the format string gets the next parsed value takes from the next parameter in the list following format. A parameter specification takes this form (square brackets indicate optional fields, angled brackets indicate required fields):

`%[*][width]<type>`

\*, width, and type may be:

- \*  
suppress assigning this value to any parameter
- width  
maximum number of characters to read; fewer will be read if white space or nonconvertible character
- type  
may be one of the following:
  - d, D, i, I  
signed integer
  - u, U  
unsigned integer
  - o, O  
octal integer
  - x, X  
hexadecimal integer
  - f, e, E, g, G  
floating point number
  - c  
character; if width was specified then this will be an array of characters of the specified length
  - s  
string
  - [abc]  
string consisting of all characters within brackets; where A- Z represents range "A" to "Z"
  - [^abc]  
string consisting of all character NOT within brackets.

Modifies any number of parameters following the format string, setting the parameters to data according to the specifications of the format string.

SEE: [Clib.vscanf\(\)](#)

---

### **Clib.vprintf()**

SYNTAX: `Clib.vprintf(formatString, valist)`

WHERE: `formatString` - string that specifies the final format.

`valist` - a variable list of arguments to be used according to

---

---

formatString.

RETURN: number - number of characters written on success, else a negative number.

DESCRIPTION: This method displays formatted output on the standard output stream, screen, using a variable number of arguments. This method is similar to `Clib.printf()` except that it takes a variable argument list using `valist`.

See `Clib.printf()` and `Clib.va_start()` for more information. The method `Clib.vprintf()` returns the number of characters written on success, else a negative number on error.

The example function acts just like a `Clib.printf()` statement except that it beeps, displays a message, beeps again, and waits a second before returning. This method could be a wrapper for the `Clib.printf()` method to display urgent messages.

SEE: `Clib.printf()`, `Clib.va_start()`

EXAMPLE: 

```
function UrgentPrintf(FormatString[ arg1 ...])
{
    // create variable arg list
    Clib.va_start(valist, FormatString);
    Screen.write("\a"); // audible beep
    // printf original statement
    var ret = Clib.vprintf(FormatString, valist);
    Screen.write("\a"); // beep again
    SElib.suspend(1000); // wait before returning
    Clib.va_end(valist); // end using valist
    return(ret); // return as printf would
}
```

---

## **Clib.vscanf()**

---

SYNTAX: `Clib.vscanf(formatString, valist)`

WHERE: `formatString` - string that specifies the final format.

`valist` - a variable list of arguments to be used according to `formatString`.

RETURN: number - input items assigned. This number may be fewer than the number of parameters requested if there is a matching failure during input.

DESCRIPTION: This method gets formatted input from the standard input stream, the keyboard, using a variable number of arguments. This method is similar to `Clib.scanf()` except that it takes a variable argument list. See `Clib.scanf()` and `Clib.va_start()` for more information.

The method `Clib.vscanf()` modifies any number of parameters following `formatString`, setting the parameters to data according to the specifications of the format string.

This method returns the number of input items assigned. This number may be fewer than the number of parameters requested if there is a matching failure during input.

---

---

The example function behaves like `Clib.scanf()`, including taking a variable number of input arguments, except that it beeps and tries again if there are zero matches:

SEE: [Clib.scanf\(\)](#)

EXAMPLE:

```
function Must_scanf(FormatString[,arg1 ...])
{
    Clib.va_start(valist, FormatString);
    // creates variable arg list
    do
    { // mimic original scanf() call
        var count = Clib.vscanf(FormatString,
                               valist);
        if ( 0 == count ) // if no match, beep
            Screen.write("\a");
    } while( 0 == count );
    // if not match, try again
    Clib.va_end(valist);
    // end using valist (optional)
    return(count);
    // return as scanf() would
}
```

---

## Time functions

The **Clib object** (like the Date object) represents time in two distinct ways: as an integral value (the number of seconds passed since January 1, 1970) and as a Time object with properties for the day, month, year, etc. This Time object is distinct from the standard JavaScript Date object. You cannot use Date object properties with a Time object or vice versa.

In the methods below, `timeObj` represents a variable in the Time object format, while `timeInt` represents an integral time value.

### Clib.asctime()

---

SYNTAX: `Clib.asctime(timeObj)`

WHERE: `timeObj` - time variable in the Time object format.

RETURN: string - the date and time extracted from a Time object, as returned by `Clib.localtime()`.

DESCRIPTION: Returns a string representing the date and time extracted from a Time object, as returned by `Clib.localtime()`. The string will have this format:

```
Mon Jul 19 09:14:22 1993
```

---

### Clib.clock()

---

SYNTAX: `Clib.clock()`

RETURN: number - the current processor tick count.

DESCRIPTION: Returns the current processor tick count. Clock value starts at 0 when ScriptEase program begins and is incremented `CLOCKS_PER_SEC` times per second.

---

---

### **Clib.ctime()**

---

**SYNTAX:** `Clib.ctime(timeInt)`  
**WHERE:** `timeInt` - an integer time value.

**RETURN:** string - the date and time extracted from a Time object, as returned by `Clib.localtime()`.

**DESCRIPTION:** This method is equivalent to: `Clib.asctime (Clib.localtime(time) )`, where `timeInt` is a `date_time` value as returned by the `Clib.time()` function.

---

### **Clib.difftime()**

---

**SYNTAX:** `Clib.difftime(timeInt0, timeInt1)`  
**WHERE:** `timeInt0` - an integer time value.  
`timeInt1` - an integer time value.

**RETURN:** number - difference between two times, in seconds.

**DESCRIPTION:** This method returns the difference in seconds between two times. `timeInt0` and `timeInt1` are integral time values as returned by the `Clib.time()` function.

---

### **Clib.gmtime()**

---

**SYNTAX:** `Clib.gmtime(timeInt)`  
**WHERE:** `timeInt` - an integer time value.

**RETURN:** object - a time object reflecting the value `timeInt` (as returned by the `Clib.time()`).

**DESCRIPTION:** Takes the integer `timeInt` (as returned by the `Clib.time()` function) and converts it to a Time object representing the current date and time expressed as Greenwich mean time. See `Clib.localtime()` for a description of the returned object.

**SEE:** [Clib.mktime\(\)](#), [Date Object](#), [Date toGMTString\(\)](#)

---

### **Clib.localtime()**

---

**SYNTAX:** `Clib.localtime(timeInt)`  
**WHERE:** `timeInt` - an integer time value.

**RETURN:** object - a time object reflecting the value `timeInt` (as returned by the `Clib.time()` function).

**DESCRIPTION:** This method returns the value `timeInt` (as returned by the `time()` function) as a Time object. Note that the Time object differs from the Date object, although they contain the same data. The Time object is for use with the other date and time functions in the `Clib object`. It has the following integer properties:

- `.tm_sec`  
second after the minute (from 0)
- `.tm_min`

---

---

minutes after the hour (from 0)

- `.tm_hour`  
hour of the day (from 0)
- `.tm_mday`  
day of the month (from 1)
- `.tm_mon`  
month of the year (from 0)
- `.tm_year`  
years since 1900 (from 0)
- `.tm_wday`  
days since Sunday (from 0)
- `.tm_yday`  
day of the year (from 0)
- `.tm_isdst`  
daylight-savings-time flag

The following function prints the current date and time on the screen and returns the day of the year, where Jan 1 is the 1st day of the year.

SEE: [Clib.mktime\(\)](#), [Date Object](#), [Date toDateString\(\)](#), [Date toLocaleDateString\(\)](#)

EXAMPLE:

```
// Show today's date
// Return day of the year in USA format
ShowToday()
{
    // get current time structure
    var tm = Clib.localtime(Clib.time());
    // display the date in USA format
    Clib.printf("Date: %02d/%02d/%02d  ",
               tm.tm_mon+1,
               tm.tm_mday, tm.tm_year % 100);
    // hour to run from 12 to 11, not 0 to 23
    var hour = tm.tm_hour % 12;
    if ( hour == 0 )
        hour = 12;
    // print current time
    Clib.printf("Time: % 2d:%02d:%02d\n", hour,
               tm.tm_min,
               tm.tm_sec);
    // return day of year, Jan. 1 is day 1
    return( tm.tm_yday + 1 );
}
```

---

### **Clib.mktime()**

SYNTAX: `Clib.mktime(timeObj)`

WHERE: `timeObj` - time variable in the Time object format.

RETURN: number - time integer, or -1 if time cannot be converted or represented.

DESCRIPTION: This method converts `timeObj` (an object as returned by [Clib.localtime\(\)](#)) to the time format returned by [Clib.time\(\)](#) (an integer). All undefined elements of `timeObj` will be set to 0 before the conversion. It returns -1 if time cannot be converted or

---

---

represented.

In other words, while `Clib.localtime()` converts from a time integer to a Time object, `Clib.mktime()` converts from a Time object to a time integer.

---

### **Clib.strftime()**

---

SYNTAX: `Clib.strftime(str, formatString, timeObj)`

WHERE: `str` - a variable to receive the formatted time string.

`formatString` - string that specifies the final format.

`timeObj` - time variable in the Time object format.

RETURN: string - a string that describes the date and/or time and stores it in the variable string.

DESCRIPTION: This method creates a string that describes the date and or time and stores it in the variable `str`. The parameter `formatString` describes what the string will look like, and `timeObj` is a time object as returned by `Clib.localtime()`.

These following conversion characters are used with `Clib.strftime()` to indicate time and date output:

- `%a`  
abbreviated weekday name (Sun)
  - `%A`  
full weekday name (Sunday)
  - `%b`  
abbreviated month name (Dec)
  - `%B`  
full month name (December)
  - `%c`  
date and time (Dec 2 06:55:15 1979)
  - `%d`  
two- digit day of the month (02)
  - `%H`  
two- digit hour of the 24- hour day (06)
  - `%I`  
two- digit hour of the 12- hour day (06)
  - `%j`  
three- digit day of the year from 001 (335)
  - `%m`  
two- digit month of the year from 01 (12)
  - `%M`  
two- digit minute of the hour (55)
  - `%p`  
AM or PM (AM)
  - `%S`  
two- digit seconds of the minute (15)
  - `%U`
-

- 
- two- digit week of year, Sunday is first day of week (48)
  - %w  
day of the week where Sunday is 0 (0)
  - %W  
two- digit week of year, Monday is first day of week (47)
  - %x  
the date (Dec 2 1979)
  - %X  
the time (06:55:15)
  - %y  
two- digit year of the century (79)
  - %Y  
the year (1979)
  - %Z  
name of the time zone, if known (EST)
  - %%  
the per cent character (%)

EXAMPLE:       // displays the full day name and month name  
                  // of the current day  
                  Clib.strftime(TimeBuf,  
                                  "Today is: %A, the month is: %B",  
                                  Clib.localtime(time()));  
                  Clib.puts(TimeBuf);

---

## **Clib.time()**

---

SYNTAX:       Clib.time([t])  
WHERE:        t - variable to receive the time returned.  
  
RETURN:       number - integer representation of the current time.  
  
DESCRIPTION:   Returns an integer representation of the current time. The format of the time is not specifically defined except that it represents the current time, to the system's best approximation, and can be used in many other time related functions. If t is supplied then it will be set to equal the returned value.

---

## **Script execution**

### **Clib.abort()**

---

SYNTAX:       Clib.abort([AbortAll])  
WHERE:        AbortAll - boolean flag as to whether to abort all levels of ScriptEase execution.  
  
RETURN:       number - EXIT\_FAILURE to the operating system.  
  
DESCRIPTION:   This method terminates a program, usually when a specified error occurs. This method causes abnormal program termination and should only be called on a fatal error. This method exits, without returning to the caller, and returns EXIT\_FAILURE to the operating system.

---

---

If the boolean `AbortAll` is `true`, this method aborts through all levels of ScriptEase interpretation. If you are in multiple levels of `SElib.interpret()`, `.abort()` aborts through all `SElib.interpret()` levels.

SEE: [Clib.assert\(\)](#)

---

### **Clib.assert()**

---

SYNTAX: `Clib.assert(test)`

WHERE: `test` - boolean flag to determine if the current file name and line number will be displayed and if the script will abort.

RETURN: `void`.

DESCRIPTION: If boolean evaluates to `false` this function will print the file name and line number to `stderr` and abort. If the assertion evaluates to `true` then the program continues. `Clib.assert()` is typically used as a debugging technique to test assumptions before executing code based on those assumptions. Unlike C, the ScriptEase implementation of `assert` does not depend upon `NDEBUG` being defined or undefined; it is always active.

SEE: [Clib.abort\(\)](#)

EXAMPLE: 

```
// The Inverse() function below returns
// the inverse of the input number (1/x):
function Inverse(x)
{
    assert(0 != x);
    return 1 / x;
}
```

---

### **Clib.atexit()**

---

SYNTAX: `Clib.atexit(function)`

WHERE: `function` - a function to be called when a script is exited. Use the actual function name or ID and not a string.

RETURN: `void`.

DESCRIPTION: This method registers a function to be called when the script ends. The variable string passed to this function is the name of a function to be called.

SEE: [Clib.exit\(\)](#)

EXAMPLE: 

```
Screen.writeln("Starting the script");

Clib.atexit(Finished);
/*
    Not:
    Clib.atexit("Finished");
*/

function Finished()
{
    Screen.writeln("Exiting the script");
} // Finished
```

---

## **Clib.exit()**

---

SYNTAX:	<code>Clib.exit(code)</code>
WHERE:	code - status number to return to the operating system.
RETURN:	number - the status code of the exit is returned to the operating system from which a script was called.
DESCRIPTION:	This method causes normal program termination. It calls all functions registered with <code>Clib.atexit()</code> , flushes and closes all open file streams, updates environment variables if applicable to this version of ScriptEase, and returns control to the OS environment with the return code of status.
SEE:	<a href="#">Clib.atexit()</a>

---

## **Clib.system()**

---

SYNTAX:	<code>Clib.system([P_SWAP,] commandString)</code>
WHERE:	<code>P_SWAP</code> - in DOS version, determines whether the ScriptEase interpreter is swapped out of normal memory.  commandString - the command string to be executed, a command as would be entered at a command prompt.
RETURN:	value - the value returned by a command processor.
DESCRIPTION:	Passes commandString to the command processor and returns whatever value was returned by the command processor. commandString may be a formatted string followed by variables according to the rules defined in <a href="#">Clib.sprintf()</a> . <ul style="list-style-type: none"><li>• DOS In the DOS version of ScriptEase, if the special argument <code>P_SWAP</code> is used then <code>SeDos.exe</code> is swapped to EMS/XMS/INT15 memory or disk while the system command is executed. This leaves almost all available memory for executing the command. See <a href="#">SElib.spawn()</a> for a discussion of <code>P_SWAP</code>.</li><li>• DOS32 The 32 bit protected mode version of DOS ignores the first parameter if it is not a string; in other words, <code>P_SWAP</code> is ignored.</li></ul>
SEE:	<a href="#">SElib.spawn()</a>

---

## **Error**

### **Clib.errno**

---

SYNTAX:	<code>Clib.errno</code>
DESCRIPTION:	The property <code>errno</code> stores diagnostic message information when a function fails to execute correctly. Many functions in the <code>Clib</code> and <code>SElib</code> objects set <code>errno</code> to non-zero in case of error to provide information about the error that is more specific. ScriptEase

---

---

implements `errno` as a macro to the internal function `_errno()`.  
This property can be accessed with `Clib.perror()` or `Clib.strerror()`.

SEE: [Clib.perror\(\)](#)

---

### **Clib.clearerr()**

---

SYNTAX: `Clib.clearerr(filePointer)`  
WHERE: `filePointer` - pointer to file for which error information is to be cleared.

RETURN: `void`.

DESCRIPTION: This method clears the error status and resets the end-of-file flags for the file associated with `filePointer`. There is no return value.

SEE: [Clib.ferror\(\)](#)

---

### **Clib.ferror()**

---

SYNTAX: `Clib.ferror(filePointer)`  
WHERE: `filePointer` - pointer to file for which error information is to be retrieved.

RETURN: number - 0 on no file error, else the current error value associated with a file operation.

DESCRIPTION: The parameter `filePointer` is a file pointer as returned by `Clib.fopen()`. This method tests and returns the error indicator for stream file. Returns 0 if no error, otherwise returns the error value.

SEE: [Clib.clearerr\(\)](#)

---

### **Clib.perror()**

---

SYNTAX: `Clib.perror([errmsg])`  
WHERE: `errmsg` - a message to describe an error condition.

RETURN: string - error message that describes the error indicated by `Clib.errno`.

DESCRIPTION: Prints and returns an error message that describes the error defined by `Clib.errno`. This method is identical to calling `Clib.strerror(Clib.errno)`. If a string variable is supplied it will be set to the string returned.

SEE: [Clib.ferror\(\)](#)

---

### **Clib.strerror()**

---

SYNTAX: `Clib.strerror(errno)`  
WHERE: `errno` - an error number to convert to a descriptive string.

---

---

**RETURN:** string - an error number converted to a descriptive string.

**DESCRIPTION:** When some functions fail to execute properly, they store a number in the `.errno` property. The number corresponds to the type of error encountered. This method converts the error number to a descriptive string and returns it.

**SEE:** [Clib.perror\(\)](#)

**EXAMPLE:**

```
// Opens a file for reading, and if it cannot
// open the file then it prints a descriptive
// message and exits the program.

function MustOpen(filename)
{
    var fh = fopen(filename, "r");
    if ( fh == null )
    {
        Clib.printf("Error:%s\n",
                    Clib.strerror(errno));
        Clib.exit(EXIT_FAILURE);
    }
    return(fh);
}
```

---

## File I/O

### **Clib.fopen()**

---

**SYNTAX:** `Clib.fopen(filename, mode)`

**WHERE:** filename - a string with a filename to open.  
mode - how or for what operations the file will be opened.

**RETURN:** number - a file pointer to the file opened, `null` in case of failure.

**DESCRIPTION:** This method opens the file specified by filename for file operations specified by mode, returning a file pointer to the file opened. `null` is returned in case of failure.

The parameter filename is a string. It may be any valid file name, excluding wildcard characters.

The parameter mode is a string composed of one or more of the following characters. For example, "r" or "rt"

- r  
open file for reading; file must already exist
- w  
open file for writing; create if doesn't exist; if file exists then truncate to zero length
- a  
open file for append; create if doesn't exist; set for writing at end- of- file
- b  
binary mode; if b is not specified then open file in text mode (end- of- line translation)
- t

---

---

text mode

- +  
open for update (reading and writing)

When a file is successfully opened, its error status is cleared and a buffer is initialized for automatic buffering of reads and writes to the file.

SEE: [Clib.fclose\(\)](#), [Clib.flock\(\)](#)

EXAMPLE:

```
// Open the text file "ReadMe"
// for text mode reading, and
// display each line in the file.

var fp = Clib.fopen("ReadMe", "r");
if ( fp == null )
    Clib.printf(
        "\aError opening file for reading.\n")
else
    while ( null != (line=Clib.fgets(fp)) )
    {
        Clib.fputs(line, stdout)
    }
Clib.fclose(fp);
```

---

### **Clib.fclose()**

---

SYNTAX: `Clib.fclose(filePointer)`

WHERE: `filePointer` - pointer to file to close.

RETURN: number - 0 on success, else EOF.

DESCRIPTION: The parameter `filePointer` is a file pointer as returned by [Clib.fopen\(\)](#). This method flushes the file buffers of a stream and closes the file. The file pointer ceases to be valid after this call. Returns zero if successful, otherwise returns EOF.

SEE: [Clib.fopen\(\)](#), [Clib.flock\(\)](#)

---

### **Clib.feof()**

---

SYNTAX: `Clib.feof(filePointer)`

WHERE: `filePointer` - pointer to file to use.

RETURN: number - 0 if at end of file, else a non-zero number.

DESCRIPTION: The parameter `filePointer` is a file pointer as returned by [Clib.fopen\(\)](#). This method returns an integer which is non-zero if the file cursor is at the end of the file, and 0 if it is NOT at the end of the file.

SEE: [Clib.fopen\(\)](#)

---

### **Clib.fflush()**

---

SYNTAX: `Clib.fflush(filePointer)`

WHERE: `filePointer` - pointer to file to use.

---

---

RETURN:	number - 0 on success, else EOF.
DESCRIPTION:	Causes any unwritten buffered data to be written to filePointer. If filePointer is null then flushes buffers in all open files. Returns zero if successful; otherwise EOF.
SEE:	<a href="#">Clib.fclose()</a>

---

### **Clib.fgetc()**

---

SYNTAX:	<code>Clib.fgetc(filePointer)</code>
WHERE:	filePointer - pointer to file to use.
RETURN:	number - EOF if there is a read error or the file cursor is at the end of the file. If there is a read error then <a href="#">Clib.ferror()</a> will indicate the error condition.
DESCRIPTION:	This method returns the next character in the file stream indicated by filePointer as a byte converted to an integer.
SEE:	<a href="#">Clib.gets()</a>

---

### **Clib.fgetpos()**

---

SYNTAX:	<code>Clib.fgetpos(filePointer, pos)</code>
WHERE:	filePointer - pointer to file to use.  pos - variable to hold the current file position.
RETURN:	number - 0 on success, else non-zero and stores an error value in <a href="#">Clib.errno</a> .
DESCRIPTION:	This method stores the current position of the file stream filePointer for future restoration using <a href="#">Clib.fsetpos()</a> . The file position will be stored in the variable pos; use it with <code>Clib.fsetpos()</code> to restore the cursor to its position.
SEE:	<a href="#">Clib.fsetpos()</a>

---

### **Clib.fgets()**

---

SYNTAX:	<code>Clib.fgets([length,] filePointer)</code>
WHERE:	length - maximum length of string.  filePointer - pointer to file to use.
RETURN:	string - the characters in a file from the current file cursor to the next newline character on success, else null.
DESCRIPTION:	This method returns a string consisting of the characters in a file from the current file cursor to the next newline character. The newline will be returned as part of the string. If there is an error or the end of the file is reached, null will be returned.  A second syntax of this function takes a number as its first parameter. This number is the maximum length of the string to be returned if no newline character was encountered.

---

---

SEE: [Clib.fgetc\(\)](#)

---

### **Clib.fprintf()**

---

SYNTAX: `Clib.fprintf(filePointer, formatString[, variables ...])`

WHERE: `filePointer` - pointer to file to use.

`formatString` - string that specifies the final format.

`variables` - values to be converted to and formatted as a string.

RETURN: number - characters written on success, else a negative number.

DESCRIPTION: This flexible function writes a formatted string to the file associated with `filePointer`. The second parameter, `formatString`, is a string of the same pattern as [Clib.sprintf\(\)](#) and [Clib.rsprintf\(\)](#).

SEE: [Clib.printf\(\)](#)

---

### **Clib.fputc()**

---

SYNTAX: `Clib.fputc(chr, filePointer)`

WHERE: `chr` - character to write to file.

`filePointer` - pointer to file to use.

RETURN: number - character written on success, else EOF.

DESCRIPTION: If `chr` is a string, the first character of the string will be written to the file indicated by `filePointer`. If `chr` is a number, the character corresponding to its unicode value will be added.

SEE: [Clib.fputs\(\)](#)

---

### **Clib.fputs()**

---

SYNTAX: `Clib.fputs(str, filePointer)`

WHERE: `str` - string to write to file.

`filePointer` - pointer to file to use.

RETURN: number - non-negative number on success, else EOF.

DESCRIPTION: This method writes the value of `str` to the file indicated by `filePointer`. Returns EOF if write error, else returns a non-negative value.

SEE: [Clib.fputc\(\)](#)

---

### **Clib.fread()**

---

SYNTAX: `Clib.fread(dstVar, varDescription, filePointer)`

WHERE: `dstVar` - variable to hold data read from file.

`varDescription` - description of the data to read, that is, how and how much.

---

---

filePointer - pointer to file to use.

RETURN: number - elements read on success, 0 on failure.

DESCRIPTION: This method reads data from an open file and stores it in dstVar. If it does not yet exist, dstVar will be created. varDescription is a variable that describes the how and how much data is to be read: if dstVar is a buffer, it will be the length of the buffer; if dstVar is an object, varDescription must be an object descriptor; and if dstVar is to hold a single datum then varDescription must be one of the following.

- UWORD8  
Stored as a byte in dstVar
- SWORD8  
Stored as an integer in dstVar
- UWORD16  
Stored as an integer in dstVar
- SWORD16  
Stored as an integer in dstVar
- UWORD24  
Stored as an integer in dstVar
- SWORD24  
Stored as an integer in dstVar
- UWORD32  
Stored as an integer in dstVar
- SWORD32  
Stored as an integer in dstVar
- FLOAT32  
Stored as a float in dstVar
- FLOAT64  
Stored as a float in dstVar
- FLOAT80  
Stored as a float in dstVar (not available in Win32)

In all cases, this function returns the number of elements read. For dstVar being a buffer, this would be the number of bytes read, up to length specified in varDescription. For dstVar being an object, this method returns 1 if the data is read or 0 if read error or end- of- file is encountered.

For example, the definition of an object might be:

```
ClientDef.Sex = UWORD8;  
ClientDef.MaritalStatus = UWORD8;  
ClientDef.Unused1 = UWORD16;  
ClientDef.FirstName = 30; ClientDef.LastName = 40;  
ClientDef.Initial = UWORD8;
```

The ScriptEase version of `Clib.fread()` differs from the standard C version in that the standard C library is set up for reading arrays of numeric values or structures into consecutive bytes in memory. In JavaScript, this is not necessarily the case.

---

---

Data types will be read from the file in a byte- order described by the current value of the `_BigEndianMode` global variable.

SEE: [Clib.fopen\(\)](#), [Clib.fwrite\(\)](#)

EXAMPLE:

```
// To read the 16-bit integer "i",
// the 32-bit float "f", and
// then 10 byte buffer "buf"
// from the open file "fp"
// use code like the following.

if ( !Clib.fread(i, SWORD16, fp) ||
     !Clib.fread(f, FLOAT32, fp) ||
     (10 != Clib.fread(buf, 10, fp)) )
{
    Clib.printf("Error reading from file.\n");
    Clib.abort();
}
```

---

### **Clib.freopen()**

---

SYNTAX: `Clib.freopen(filename, mode, filePointer)`

WHERE: `filename` - a string with a filename to open.

`mode` - how or for what operations the file will be opened.

`filePointer` - pointer to file to use.

RETURN: number - file pointer on success, else `null`.

DESCRIPTION: This method closes the file associated with `filePointer`, ignoring any close errors, opens `filename` according to `mode`, as with [Clib.fopen\(\)](#), and reassociates `filePointer` with the new file specification. This method is commonly used to redirect one of the pre-defined file handles (`stdout`, `stderr`, or `stdin`) to or from a file.

The method returns a copy of the modified `filePointer`, or `null` if it fails.

The example code calls `ScriptEase` for DOS with no parameters, which causes a help screen to be printed, and redirects `stdout` to a file `cenvi.out` so that `cenvi.out` will contain the text of the `ScriptEase` help screens.

SEE: [Clib.fopen\(\)](#)

EXAMPLE:

```
if ( null == Clib.freopen("cenvi.out", "w", stdout) )
    Clib.printf("Error redirecting stdout\n");
else
    Clib.system("SEDOS");
```

---

### **Clib.fscanf()**

---

SYNTAX: `Clib.fscanf(filePointer, formatString[, variables ...])`

WHERE: `filePointer` - pointer to file to use.

`formatString` - string that specifies the final format.

`variables` - values to be converted to and formatted as a string.

---

---

**RETURN:** number - input items assigned on success, else EOF.

**DESCRIPTION:** This flexible function reads input from the file indicated by `filePointer` and stores in parameters following `formatString` according the character combinations in the format string, which indicate how the file data is to be read and stored. The file must be open, with read access. It returns the number of input items assigned. This number may be fewer than the number of parameters requested if there was a matching failure. If there is an input failure, before the conversion occurs, this function returns EOF.

See [Clib.scanf\(\)](#) for a description of this format string. The parameters following the format string will be set to data according to the specifications of the format string.

**SEE:** [Clib.scanf\(\)](#)

**EXAMPLE:**

```
// Given the following text file, weight.dat:
// Crow, Barney      180
// Claus, Santa     306
// Mouse, Mickey     2
// the following code:

var fp = Clib.fopen("weight.dat", "r");
var FormatString = "%[,] %*c %s %d\n";
while (3 == Clib.fscanf(fp, FormatString,
    LastName, Firstname, weight))
    Clib.printf("%s %s weighs %d pounds.\n",
        FirstName, LastName, weight);
Clib.fclose(fp);

// results in the following output:
// Barney Crow weighs 180 pounds.
// Santa Claus weighs 306 pounds.
// Mickey Mouse weighs 2 pounds.
```

---

### **Clib.fseek()**

---

**SYNTAX:** `Clib.fseek(filePointer, offset[, mode])`

**WHERE:** `filePointer` - pointer to file to use.

`offset` - number of bytes past or offset from the point indicated by mode.

`mode` - file position to use as a starting point. Default is `SEEK_SET` and may be one of the following:

- `SEEK_CUR`  
seek is relative to the current position of the file
- `SEEK_END`  
position is relative from the end of the file
- `SEEK_SET`  
position is relative to the beginning of the file

**RETURN:** number - 0 on success, else non-zero.

**DESCRIPTION:** Set the position of the file pointer of the open file stream `filePointer`. The parameter `offset` is a number indicating how

---

---

many bytes the new position will be past the starting point indicated by mode.

If mode is not supplied then absolute offset from the beginning of file, `SEEK_SET`, is assumed. For text files, not opened in binary mode, the file position may not correspond exactly to the byte offset in the file.

SEE: [Clib.fsetpos\(\)](#), [Clib.ftell\(\)](#)

---

### **Clib.fsetpos()**

---

SYNTAX: `Clib.fsetpos(filePointer, pos)`

WHERE: `filePointer` - pointer to file to use.

`pos` - position in file to set.

RETURN: number - zero on success, otherwise returns non-zero and stores an error value in `Clib.errno`.

DESCRIPTION: This method sets the current file stream pointer to the value defined by `pos`, which must be a value obtained from a previous call to [Clib.fgetpos\(\)](#) on the same open file. Returns zero for success, otherwise returns non-zero and stores an error value in [Clib.errno](#).

SEE: [Clib.fseek\(\)](#)

---

### **Clib.ftell()**

---

SYNTAX: `Clib.ftell(filePointer)`

WHERE: `filePointer` - pointer to file to use.

RETURN: number - current value of the file position indicator, or -1 if there is an error, in which case an error value will be stored in `Clib.errno`.

DESCRIPTION: This method sets the position offset of the file pointer of an open file stream from the beginning of the file. For text files, not opened in binary mode, the file position may not correspond exactly to the byte offset in the file. Returns the current value of the file position indicator, or -1 if there is an error, in which case an error value will be stored in [Clib.errno](#).

SEE: [Clib.fseek\(\)](#)

---

### **Clib.fwrite()**

---

SYNTAX: `Clib.fwrite(srcVar, varDescription, filePointer)`

WHERE: `srcVar` - variable to hold data to write to file.

`varDescription` - description of the data to write, that is, how and how much.

`filePointer` - pointer to file to use.

RETURN: number - elements written on success, else 0 if a write error

---

---

occurs.

DESCRIPTION: This method writes the data in `srcVar` to the file indicated by `filePointer` and returns the number of elements written. 0 will be returned if a write error occurs. Use `Clib.ferror()` to get more information about the error. `varDescription` is a variable that describes the how and how much data is to be read. If `srcVar` is a buffer, it will be the length of the buffer. If `srcVar` is an object, `varDescription` must be an object descriptor. If `srcVar` is to hold a single datum then `varDescription` must be one of the values listed in the description for `Clib.fread()`.

The ScriptEase version of `Clib.fwrite()` differs from the standard C version in that the standard C library is set up for writing arrays of numeric values or structures from consecutive bytes in memory. This is not necessarily the case in JavaScript.

SEE: [Clib.fread\(\)](#)

EXAMPLE: 

```
// To write the 16_bit integer "i",
// the 32_bit float "f", and
// then 10_byte buffer "buf" into open file "fp",
// use the following code.

if (!Clib.fwrite(i, SWORD16, fp) ||
    !Clib.fwrite(f, FLOAT32, fp) ||
    (10 != fwrite(buf, 10, fp)))
{
    Clib.printf("Error writing to file.\n");
    Clib.abort();
}
```

---

## **Clib.getc()**

---

SYNTAX: `Clib.getc(filePointer)`

WHERE: `filePointer` - pointer to file to use.

RETURN: number - on success, the next character, as an unsigned byte converted to an integer, in a file. Else EOF if a read error or at the end of file.

DESCRIPTION: This method is identical to `Clib.fgetc()`. It returns the next character in a file as an unsigned byte converted to an integer. Returns EOF if there is a read error or if at the end of the file. If there is a read error then `Clib.ferror()` will indicate the error condition.

SEE: [Clib.gets\(\)](#)

---

## **Clib.putc()**

---

SYNTAX: `Clib.putc(chr, filePointer)`

WHERE: `chr` - character to write to file.  
`filePointer` - pointer to file to use.

RETURN: number - character written on success, else EOF on write error.

DESCRIPTION: This method writes the character `chr`, converted to a byte, to an

---

---

output file stream. This method is identical to `Clib.fputc()`. It returns `chr` on success and `EOF` on a write error.

SEE: [Clib.fputc\(\)](#)

---

### **Clib.remove()**

---

SYNTAX: `Clib.remove(filename)`

WHERE: `filename` - the name of the file to delete from a disk.

RETURN: number - 0 on success, else non-zero.

DESCRIPTION: Delete a file with the filename provided.

SEE: [Clib.rename\(\)](#), [Clib.fopen\(\)](#)

---

### **Clib.rename()**

---

SYNTAX: `Clib.rename(oldFilename, newFilename)`

WHERE: `oldFilename` - current name of file on disk to be renamed.

`newFilename` - new name for file on disk.

RETURN: number - 0 on success, else non-zero.

DESCRIPTION: This method renames `oldFilename` to `newFilename`. Both `oldFilename` and `newFilename` are strings. Returns zero if successful and non-zero for failure.

SEE: [Clib.remove\(\)](#)

---

### **Clib.rewind()**

---

SYNTAX: `Clib.rewind(filePointer)`

WHERE: `filePointer` - pointer to file to use.

RETURN: void.

DESCRIPTION: This method sets the file cursor to the beginning of file. This call is the same as `Clib.fseek(filePointer, 0, SEEK_SET)` except that it also clears the error indicator for this stream.

SEE: [Clib.fseek\(\)](#)

---

### **Clib.tmpfile()**

---

SYNTAX: `Clib.tmpfile()`

RETURN: number - on success, a file pointer to a temporary binary file that will automatically be removed when it is closed or when the program exits, else `null` on failure.

DESCRIPTION: This method returns the file pointer of a temporary binary file that will automatically be removed when it is closed or when the program exits. Returns `null` if the function fails.

SEE: [Clib.tmpnam\(\)](#)

---

## **Clib.tmpnam()**

---

**SYNTAX:** `Clib.tmpnam([str])`  
**WHERE:** `str` - a variable to hold the name of a temporary file.

**RETURN:** string - a valid and unique filename.

**DESCRIPTION:** This method creates a string that is a valid file name that is not the same as the name of any existing file and not the same as any filename returned by this function during execution of this program. If `str` is supplied it will be set to the string returned by this function.

**SEE:** [Clib.tmpfile\(\)](#)

---

## **Clib.ungetc()**

---

**SYNTAX:** `Clib.ungetc(chr, filePointer)`  
**WHERE:** `chr` - character to write to file.  
`filePointer` - pointer to file to use.

**RETURN:** number - on success, the character put back into a file stream, else EOF.

**DESCRIPTION:** This method pushes character `chr` back into an input stream. When `chr` is put back, it is converted to a byte and is again in an input stream for subsequent retrieval. Only one character is guaranteed to be pushed back. The method returns `chr` on success, else EOF on failure.

**SEE:** [Clib.getc\(\)](#)

---

## **Directory**

### **Clib.chdir()**

---

**SYNTAX:** `Clib.chdir(dirpath)`  
**WHERE:** `dirpath` - directory specification to which to change.

**RETURN:** number - 0 on success, else -1.

**DESCRIPTION:** This method changes the directory for a script from its current directory to the directory specified in the parameter `dirpath`. The specified directory may be an absolute or relative path specification.

**SEE:** [Clib.getcwd\(\)](#)

---

### **Clib.getcwd()**

---

**SYNTAX:** `Clib.getcwd()`  
**RETURN:** string - complete path of the current working directory for a script.

**DESCRIPTION:** This method returns the complete path of the current working directory for a script.

---

---

SEE: [Clib.chdir\(\)](#)

---

## **Clib.flock()**

---

SYNTAX: `Clib.flock(filePointer, lockFlag)`

WHERE: `filePointer` - pointer to file to use.

`lockFlag` - determines which locking operation to perform on a file. The flags are:

- `LOCK_EX`  
File lock exclusive (equivalent to `LOCK_SH` in Windows)
- `LOCK_SH`  
File lock share (equivalent to `LOCK_EX` in Windows)
- `LOCK_NB`  
File lock non-blocking (bitwise or with `LOCK_EX` or `LOCK_SH`)
- `LOCK_UN`  
File unlock

RETURN: number - 0 on success, else -1 on failure.

DESCRIPTION: This method allows a file to be locked or unlocked, which is a capability that is often important in a multi-tasking operating system.

The ability to lock and unlock access to a file varies among operating systems. For normal usage on most systems, the operating system handles all necessary locking and administration of sharing privileges for files. However, if a scripter needs extra control over files, ScriptEase provides the ability. For example, a script might use files to hold data while it is running but does not need to keep the files open during all phases of script execution. By locking and unlocking such files, a scripter ensures that these files are not altered while a script is running.

SEE: [Clib.fopen\(\)](#), [Clib.fclose\(\)](#)

EXAMPLE: 

```
// The following fragment opens a file and
// then locks it for exclusive use without blocking
// further execution of the script.
```

```
var fp = Clib.fopen("myfile", "r");
Clib.flock(fp, LOCK_EX | LOCK_NB);
    // Use the file
Clib.flock(fp, LOCK_UN);
Clib.fclose(fp);
```

---

## **Clib.mkdir()**

---

SYNTAX: `Clib.mkdir(dirpath)`

WHERE: `dirpath` - directory specification to make.

RETURN: number - 0 on success, else -1.

DESCRIPTION: This method creates the directory specified in the parameter

---

---

dirpath. The specified directory may be an absolute or relative path specification.

SEE: [Clib.rmdir\(\)](#), [Clib.chdir\(\)](#)

---

## **Clib.rmdir()**

---

SYNTAX: `Clib.rmdir(dirpath)`

WHERE: dirpath - directory specification to delete.

RETURN: number - 0 on success, else -1.

DESCRIPTION: This method deletes the directory specified by the parameter dirpath.

SEE: [Clib.mkdir\(\)](#), [Clib.remove\(\)](#)

---

## **Sorting**

### **Clib.bsearch()**

---

SYNTAX: `Clib.bsearch(key, array[, elementCount],  
compareFunction)`

WHERE: key - value for which to search.

array - beginning of array to search.

elementCount - number of elements to search. Default is the entire array.

compareFunction - function used to compare key with each element searched in the array.

RETURN: value - the element in an array if found, else `null` if not found.

DESCRIPTION: This method looks for an array variable that matches the key, returning it if found and `null` if not. It will only search through positive array members (array members with negative indices will be ignored). The compareFunction must receive the key variable as its first argument and a variable from the array as its second argument. If elementCount is not supplied then it will search the entire array. The elementCount is limited to 64K for 16-bit version of ScriptEase.

SEE: [Clib.qsort\(\)](#)

EXAMPLE: 

```
// This example creates a two dimensional array
// that pairs a name with a favorite food.
// A name is searched for. The name and paired
// food is displayed.
```

```
var Found;
var Key;
var list;
```

```
    // create array of names and favorite food
var list =
{
    {"Marge",    "salad"},
```

---

---

```

        {"Lisa",      "tofu"},
        {"Homer",    "sugar"},
        {"Bart",     "anything"},
        {"Itchy",    "cats"},
        {"Scratchy", "anything from the garbage"}
    };
    // sort the list
    Clib.qsort(list, ListCompareFunction);

    Key[0] = "marge";
    // search for the name Marge in the list
    Found = Clib.bsearch(Key, list, ListCompareFunction);
    // display name, or not found

    if (Found != null)
        Clib.printf("%s's favorite food is %s\n",
                    Found[0], Found[1])
    else
        Clib.puts("Could not find name in list.");

    // This compare function is used to sort
    // the array and to find a name.
    // The sort and search are case insensitive.
    function ListCompareFunction(Item1, Item2)
    {
        return Clib.strcmpi(Item1[0], Item2[0]);
    }

```

---

## Clib.qsort()

---

SYNTAX: `Clib.qsort(array[, elementCount], compareFunction)`

WHERE: `array` - array to sort.

`elementCount` - number of elements to sort. Default is the entire array.

`compareFunction` - function used to compare key with each element searched in the array.

RETURN: `void`.

DESCRIPTION: This method sorts elements in an array, starting from index 0 to `elementCount-1`. If `elementCount` is not supplied, then it will sort the entire array. This method differs from the `Array.sort()` method in that it can sort automatically created arrays, whereas `Array.sort()` only works with arrays explicitly created with a new `Array()` statement.

The value of `elementCount` is limited to 64K.

SEE: [Clib.bsearch\(\)](#), [Array\(\)](#)

EXAMPLE:

```

// Create a list of color names,
// sort the list in reverse alphabetical order,
// case insensitive, and display the list.

    // initialize an array of colors
    var colors = {"yellow", "Blue", "GREEN", "purple",
                "RED", "BLACK", "white", "orange"};

    // sort the list ReverseColorSorter function

```

---

---

```

Clib.qsort(colors, ReverseColorSorter);

    // display the sorted colors
for (var i = 0; i < getArrayLength(colors); i++)
    Clib.puts(colors[i]);

function ReverseColorSorter(color1,color2)
    // do a simple case insensitive string
    // comparison, and reverse the results too
{
    var CompareResult = Clib.stricmp(color1,color2)
    return -CompareResult;
}

// The output is:
// yellow
// white
// RED
// purple
// orange
// GREEN
// Blue
// BLACK

```

---

## Environment variables

### **Clib.getenv()**

---

**SYNTAX:** Clib.getenv([variableName])

**WHERE:** variableName - the name of an environment variable.

**RETURN:** string - a string representation of the value of an environment variable on success. If no variableName is passed, an array of all environment variable names. On failure, returns null.

**DESCRIPTION:** If the parameter variableName is supplied, this method returns the value of a similarly named environment variable as a string, if the variable exists, and null if VariableName does not exist. If no name is supplied. then it returns an array of all environment variable names, ending with a null element.

**SEE:** [Clib.putenv\(\)](#)

**EXAMPLE:**

```

// Print the existing environment variables,
// in "EVAR=Value" format,
// sorted alphabetically.

    // get array of all environment variable names
var EnvList = Clib.getenv();
    // sort array alphabetically
Clib.qsort(EnvList, getArrayLength(EnvList),
    Clib.stricmp);
    // display each element in ENV=VALUE format
for ( var lIdx = 0; EnvList[lIdx]; lIdx++ )
    Clib.printf("%s=%s\n", EnvList[lIdx],
        Clib.getenv(EnvList[lIdx]));

```

---

### **Clib.putenv()**

---

**SYNTAX:** Clib.putenv(variableName, stringValue)

---

---

WHERE:	variableName - the name of an environment variable. stringValue - new value for environment variable variableName.
RETURN:	number - 0 on success, else -1.
DESCRIPTION:	This method sets the environment variable variableName to the value of stringValue. If stringValue is null then variableName is removed from the environment. For those operating systems in which ScriptEase can alter the parent environment (DOS or OS/2 when invoked with <i>SD.bat</i> or <i>SEset.cmd</i> ) the variable setting will still be valid when ScriptEase exits; otherwise, the variable change applies only to the ScriptEase code and to child processes of the ScriptEase program. Returns - 1 if there is an error, else 0.
SEE:	<a href="#">Clib.getenv()</a>

---

## Character classification

JavaScript does not have a true character type. For the character classification routines, a chr is actually a single character string. Thus, actual programming usage is very much like C. For example, in the following fragment both [Clib.isalnum\(\)](#) statements work properly.

```
var t = Clib.isalnum('a');
Screen.writeln(t);

var s = 'a';
var t = Clib.isalnum(s);
Screen.writeln(t);
```

This fragment displays the following.

```
true
true
```

In the following fragment, both [Clib.isalnum\(\)](#) statements cause errors since the arguments to them are strings with more than one character.

```
var t = Clib.isalnum('ab');
Screen.writeln(t);

var s = 'ab';
var t = Clib.isalnum(s);
Screen.writeln(t);
```

All character classification methods return booleans: true or false.

### **Clib.isalnum()**

---

SYNTAX:	<code>Clib.isalnum(chr)</code>
WHERE:	chr - a character, a single character string.
RETURN:	boolean - true if chr is in: A-Z, a-z, or 0-9. Else false.
DESCRIPTION:	Returns true if chr is a character in one of the following sets: A-Z, a-z, or 0-9.

---

---

**Clib.isalpha()**

---

SYNTAX: `Clib.isalpha(chr)`  
WHERE: `chr` - a character, a single character string.  
RETURN: boolean - `true` if `chr` is in: A-Z or a-z. Else `false`.  
DESCRIPTION: Returns `true` if `chr` is an alphabetic character in one of the following sets of characters: A-Z or a-z.

---

---

**Clib.isascii()**

---

SYNTAX: `Clib.isascii(chr)`  
WHERE: `chr` - a character, a single character string.  
RETURN: boolean - `true` if `chr` is in ASCII: 0-127.  
DESCRIPTION: Returns `true` if `chr` is an ASCII character in the following set of codes: 0-127.

---

---

**Clib.iscntrl()**

---

SYNTAX: `Clib.iscntrl(chr)`  
WHERE: `chr` - a character, a single character string.  
RETURN: boolean - `true` if `chr` is in ASCII: 0-31 or 127.  
DESCRIPTION: Returns `true` if `chr` is a control character in the set of ASCII characters. Control characters are in one of the following sets of codes: 0-31 or 127.

---

---

**Clib.isdigit()**

---

SYNTAX: `Clib.isdigit(chr)`  
WHERE: `chr` - a character, a single character string.  
RETURN: boolean - `true` if `chr` is in: 0-9.  
DESCRIPTION: Returns `true` if `chr` is a decimal digit in the following set of characters: 0-9.

---

---

**Clib.isgraph()**

---

SYNTAX: `Clib.isgraph(chr)`  
WHERE: `chr` - a character, a single character string.  
RETURN: boolean - `true` if `chr` is a printable character.  
DESCRIPTION: Returns `true` if `chr` is a printable character excluding the space character " ", code 32.

---

---

**Clib.islower()**

---

SYNTAX: `Clib.islower(chr)`  
WHERE: `chr` - a character, a single character string.  
RETURN: boolean - `true` if `chr` is in: a-z.

---

---

DESCRIPTION: Returns `true` if `chr` is a lowercase character in the following set of characters: a- z

---

### **Clib.isprint()**

---

SYNTAX: `Clib.isprint(chr)`

WHERE: `chr` - a character, a single character string.

RETURN: boolean - `true` if `chr` a printable ASCII code in: 32-126.

DESCRIPTION: Returns `true` if `chr` is a printable character in the following set of codes: 32-126.

---

### **Clib.ispunct()**

---

SYNTAX: `Clib.ispunct(chr)`

WHERE: `chr` - a character, a single character string.

RETURN: boolean - if `chr` is a punctuation character code in: 32-47, 58-63, 91-96, or 123-126.

DESCRIPTION: Returns `true` if `chr` is a punctuation character in one of the following sets of codes: 32-47, 58-63, 91-96, or 123-126.

---

### **Clib.isspace()**

---

SYNTAX: `Clib.isspace(chr)`

WHERE: `chr` - a character, a single character string.

RETURN: boolean - `true` if `chr` is a white space in ASCII: 9, 10, 11, 12, 13, or 32.

DESCRIPTION: Returns `true` if `chr` is a white space character, that is, one of the following codes: 9, 10, 11, 12, 13, or 32 (horizontal tab, new line, vertical tab, form feed, carriage return, or space).

---

### **Clib.isupper()**

---

SYNTAX: `Clib.isupper(chr)`

WHERE: `chr` - a character, a single character string.

RETURN: boolean - `true` if `chr` is in: A-Z.

DESCRIPTION: Returns `true` if `chr` is an uppercase character in the following set of characters: A- Z.

---

### **Clib.isxdigit()**

---

SYNTAX: `Clib.isxdigit(chr)`

WHERE: `chr` - a character, a single character string.

RETURN: boolean - `true` if `chr` is in: 0-9, A-F, or a-f.

DESCRIPTION: Returns `true` if `chr` is a hexadecimal digit in one of the following sets of characters: 0-9, A-F, or a-f.

---

## String manipulation

### **Clib.rsprintf()**

---

**SYNTAX:** `Clib.rsprintf(formatString[, variables ...])`  
**WHERE:** `formatString` - string that specifies the final format.  
  
`variables` - values to be converted to and formatted as a string.

**RETURN:** string - formatted according to `formatString` using any variables passed.

**DESCRIPTION:** This method returns a formatted string. It is similar to `Clib.printf()`, except that a string is returned instead of printed.

**SEE:** [Clib.printf\(\)](#)

**EXAMPLE:**

```
// If in a script you had a line:

Clib.printf("%s has seen %s %d times.\n", name,
            movie, timesSeen);

// and you wanted to pass the resulting string
// as a parameter to a function, you could do it
// as follows.

func(Clib.rsprintf("%s has seen %s %d times.\n",
                  name, movie, timesSeen));

// The following lines of code achieve
// the same result, that is, create
// a string variable named word that contains
// the string "Who is #1?".

var word
word = Clib.rsprintf("Who is #%d?", 3-2);
Clib.sprintf(word, "Who is #%d?", 3-2);
```

---

### **Clib.rvsprintf()**

---

**SYNTAX:** `Clib.rvsprintf(formatString, valist)`  
**WHERE:** `formatString` - string that specifies the final format.  
  
`valist` - a variable list of arguments to be used according to `formatString`.

**RETURN:** string - specified by `formatString` on success, else EOF on error.

**DESCRIPTION:** This method returns formatted output using the variable argument list represented by the parameter `valist`, a Blob. This method is similar to `Clib.sprintf()` except that it takes a variable argument list and returns a formatted string based on the arguments, rather than storing it in a string buffer. See `Clib.sprintf()` and `Clib.va_start()` for more information. The method `Clib.rvsprintf()` returns a string specified by `formatString` on success, else EOF on error.

**SEE:** [Clib.sprintf\(\)](#), [Clib.vprintf\(\)](#)

---

## **Clib.sscanf()**

---

**SYNTAX:** `Clib.sscanf(str, formatString[, variables ...])`  
**WHERE:** `str` - string holding the data to read into variables according to `formatString`.  
`formatString` - specifies how to read and store data in variables.  
`variables` - list of variables to hold data input according to `formatString`.

**RETURN:** number - input items assigned. May be lower than the number of items requested if there is a matching failure.

**DESCRIPTION:** This flexible method reads data from a string and stores it in variables passed as parameters following `formatString`. The parameter `formatString` specifies how data is read and stored in variables. See [Clib.scanf\(\)](#) for details about `formatString`.  
`Clib.scanf()` reads data from the standard input stream, whereas this method, [Clib.sscanf\(\)](#) reads data from a string.

**SEE:** [Clib.scanf\(\)](#), [Clib.fscanf\(\)](#), [Clib.vscanf\(\)](#)

---

## **Clib.sprintf()**

---

**SYNTAX:** `Clib.sprintf(str, formatString[, variables ...])`  
**WHERE:** `str` - to hold the formatted output.  
`formatString` - string that specifies the final format.  
`variables` - values to be converted to and formatted as a string.

**RETURN:** number - characters written to string on success, else EOF on failure.

**DESCRIPTION:** This method writes output to the string variable specified by `str` according to `formatString`, and returns the number of characters written or EOF if there was an error. The parameter `formatString` may contain character combinations indicating how following parameters are to be written. The parameter `str` need not be previously defined. It will be created large enough to hold the result.  
The format string may contain character combinations indicating how following parameters are to be treated. Characters are handled normally until a percent character, %, is reached. The percent % indicates that a value is to be written from the variables following the format string. See [Clib.printf\(\)](#) for a complete description of `formatString`.

**SEE:** [Clib.printf\(\)](#)

**EXAMPLE:**

```
// Each of the following lines shows  
// a sprintf example followed  
// by the resulting string.  
  
Clib.sprintf(testString, "I count: %d %d %d.",1,2,3)  
  
//      "I count: 1 2 3"
```

---

---

```
var a = 1;
var b = 2;
Clib.sprintf(testString, "%d %d %d", a, b, a+b)

//      "1 2 3"
```

---

## **Clib.strcat()**

---

**SYNTAX:** `Clib.strcat(dstStr, srcStr)`

**WHERE:** `dstStr` - destination string to which to add `srcStr` and to hold the final result.

`srcStr` - source string to append to `dstStr`.

**RETURN:** string - the resulting string from concatenating `dstStr` and `srcStr`.

**DESCRIPTION:** This method appends `srcStr` string onto the end of `dstStr` string. The `dstStr` string is made big enough to hold `srcStr`, and a terminating null byte. In ScriptEase, a string copy is safe, so that you can copy from one part of a string to another part of itself.

The return is the value of `dstStr`, that is, a variable pointing to the `dstStr` array starting at `dstStr[0]`.

**SEE:** [Clib.strepy\(\)](#), [Clib.memcpy\(\)](#)

**EXAMPLE:**

```
// The result of the following code is:
// Giant == "Fee Fie Foe Fum"

var Giant = "Fee";
    // add Fie
Clib.strcat(Giant, " Fie");
    // add Foe
Clib.strcat(Giant, " Foe");
    // add Fum
Clib.strcat(Giant, " Fum");
```

---

## **Clib strchr()**

---

**SYNTAX:** `Clib strchr(str, chr)`

**WHERE:** `str` - string to search for a character.

`chr` - character to search for.

**RETURN:** string - beginning at the point in string where `chr` is found, else null if is not found..

**DESCRIPTION:** This method searches the parameter `str` for the character `chr`. It returns a variable indicating the first occurrence of `chr` in `str`, else it returns null if `chr` is not found in `str`.

**SEE:** [Clib.strstr\(\)](#), [String indexOf\(\)](#)

**EXAMPLE:**

```
// The following code fragment:

var str = "I can't stand soggy cereal."
var substr = Clib strchr(str, 's');
Clib.printf("str = %s\n", str);
Screen.writeln("substr = " + substr);
```

---

---

```
// results in the following output.  
// str = I can't stand soggy cereal.  
// substr = stand soggy cereal.
```

---

### **Clib.strcmp()**

---

**SYNTAX:** `Clib.strcmp(str1, str2)`  
**WHERE:** `str1` - first string to compare.  
`str2` - second string to compare

**RETURN:** number - negative, zero, or positive according to the following rules:

- `< 0` if `str1` is less than `str2`
- `= 0` if `str1` is the same as `str2`
- `> 0` if `str1` is greater than `str2`

**DESCRIPTION:** This method does a case- sensitive comparison of the characters of `str1` with `str2` until there is a mismatch or a terminating `null` byte is reached.

**SEE:** [Clib.strcmpi\(\)](#), [Clib.stricmp\(\)](#), `==`, `===`

---

### **Clib.strcmpi()**

---

**SYNTAX:** `Clib.strcmpi(str1, str2)`  
**WHERE:** `str1` - first string to compare.  
`str2` - second string to compare

**RETURN:**

- `< 0` if `str1` is less than `str2`
- `= 0` if `str1` is the same as `str2`
- `> 0` if `str1` is greater than `str2`

**DESCRIPTION:** This method does a case- insensitive comparison of the characters of `str1` with `str2` until there is a mismatch or a terminating `null` byte is reached.

**SEE:** [Clib.strcmp\(\)](#), [Clib.stricmp\(\)](#), `==`, `===`

---

### **Clib.strcpy()**

---

**SYNTAX:** `Clib.strcpy(dstStr, srcStr)`  
**WHERE:** `dstStr` - destination string to which the source string will be copied.  
`srcStr` - source string to copy to destination string.

**RETURN:** string - the value of `dstStr` after the copy process.

**DESCRIPTION:** This method copies bytes from `srcStr` to `dstStr`, up to and including the terminating `null` character. If `dstStr` is not already defined, then it is defined as a string. It is safe to copy from one part of a string to another part of the same string.

The return is the value of `dstStr`, that is, a variable pointing to the `dstStr` array starting at `dstStr[0]`.

---

---

SEE: [Clib.strncpy\(\)](#), =

---

## **Clib.strcspn()**

---

SYNTAX: `Clib.strcspn(str, chrSet)`

WHERE: `str` - string to be searched.

`chrSet` - set of characters to search for.

RETURN: number - offset into `str` to a found character on success, else the length of `str`.

DESCRIPTION: This method searches the parameter string for any of the characters in the string `chrSet` and returns the offset of that character. If no matching characters are found, it returns the length of the string. This method is similar to [Clib.strpbrk\(\)](#), except that `Clib.strcspn()` returns the offset number, or index, for the first character found, while `Clib.strpbrk()` returns the string beginning at that character.

SEE: [Clib.strpbrk\(\)](#)

EXAMPLE: 

```
// The following fragment demonstrates
// the difference between Clib.strcspn() and
// Clib.strpbrk().

var string =
    "There's more than one way to skin a cat.";
var rStrpbrk = Clib.strpbrk(string, "dxb8w9k!");
var rStrcspn = Clib.strcspn(string, "dxb8w9k!");
Clib.printf("The string is: %s\n", string);
Clib.printf("\nstrpbrk returns a string: %s\n",
    rStrpbrk);
Clib.printf("\nstrcspn returns an integer: %d\n",
    rStrcspn);
Clib.printf("string +strcspn = %s\n", string +
    rStrcspn); Clib.getch();

// And results in the following output:
// The string is:
// There's more than one way to skin a cat.
// strpbrk returns a string: way to skin a cat.
// strcspn returns an integer: 22
// string +strcspn = way to skin a cat
```

---

## **Clib.stricmp()**

---

SYNTAX: `Clib.stricmp(str1, str2)`

WHERE: `str1` - first string to compare.

`str2` - second string to compare

RETURN: 

- `< 0` if `str1` is less than `str2`
- `= 0` if `str1` is the same as `str2`
- `> 0` if `str1` is greater than `str2`

DESCRIPTION: This method does a case- insensitive comparison of the characters of `str1` with `str2` until there is a mismatch or a terminating null byte is reached.

---

---

SEE: [Clib.strptime\(\)](#), [Clib.strptime\(\)](#), [==](#), [===](#)

---

### **Clib.strlen()**

---

SYNTAX: `Clib.strlen(str)`

WHERE: `str` - string to find length of.

RETURN: number - the number of characters in `str`, not including the terminating `null` character.

DESCRIPTION: This method returns the length of parameter `str`. The length property of JavaScript strings is similar. The difference between `Clib.strlen(str)` and **String length** is that `length` counts `null` characters as part of a string, whereas `Clib.strlen()` considers them markers indicating the end of the string and does not include them or any characters which follow them as part of a string.

The return is the number of characters, bytes, in `str`, starting from the character at `str[0]` and ending before the terminating `null` byte.

SEE: [String length](#)

---

### **Clib.strlwr()**

---

SYNTAX: `Clib.strlwr(str)`

WHERE: `str` - string in which to change case of characters to lowercase.

RETURN: string - the value of `str` after conversion of case.

DESCRIPTION: This method converts all uppercase letters in `str` to lowercase, starting at `str[0]` and ending before the terminating `null` byte. The return is the value of `str`, that is, a variable pointing to the start of `str` at `str[0]`.

SEE: [Clib.strupr\(\)](#), [String toLowerCase\(\)](#)

---

### **Clib.strncat()**

---

SYNTAX: `Clib.strncat(dstStr, srcStr, maxlen)`

WHERE: `dstStr` - destination string to which to add `srcStr` and to hold the final result.

`srcStr` - source string to append to `dstStr`.

`maxLen` - maximum number of characters to append from `srcStr`.

RETURN: string - the value of the destination string after the source string characters have been appended.

DESCRIPTION: This method appends up to `maxLen` bytes of `srcStr` onto the end of `dstStr`. Characters following a `null` byte in `srcStr` are not copied. The `dstStr` array is made big enough to hold:

`Clib.min( Clib.strlen(srcStr), maxlen)`

---

---

characters and a terminating `null` character. The final value of `dstStr` is returned.

SEE: [Clib.strcat\(\)](#)

---

### **Clib.strncmp()**

---

SYNTAX: `Clib.strncmp(str1, str2, maxLen)`

WHERE: `str1` - first string to compare.

`str2` - second string to compare

`maxLen` - maximum number of characters to use for comparison.

RETURN: number - negative, zero, or positive according to the following rules:

- `< 0` if `str1` is less than `str2`
- `= 0` if `str1` is the same as `str2`
- `> 0` if `str1` is greater than `str2`

DESCRIPTION: This method compares up to `maxLen` bytes of `str1` against `str2` until there is a mismatch or the terminating `null` byte is reached. The comparison is case-sensitive. The comparison ends when `maxLen` bytes have been compared or when a terminating `null` byte has been compared, whichever comes first.

SEE: [Clib.strncmpi\(\)](#), [Clib.strnicmp\(\)](#), `==`, `===`

---

### **Clib.strncmpi()**

---

SYNTAX: `Clib.strncmpi(str1, str2, maxLen)`

WHERE: `str1` - first string to compare.

`str2` - second string to compare

`maxLen` - maximum number of characters to use for comparison.

RETURN: number - negative, zero, or positive according to the following rules:

- `< 0` if `str1` is less than `str2`
- `= 0` if `str1` is the same as `str2`
- `> 0` if `str1` is greater than `str2`

DESCRIPTION: This method compares up to `maxLen` bytes of `str1` against `str2` until there is a mismatch or the terminating `null` byte is reached. The comparison is case-insensitive. The comparison ends when `maxLen` bytes have been compared or when a terminating `null` byte has been compared, whichever comes first.

SEE: [Clib.strncmp\(\)](#), [Clib.strnicmp\(\)](#), `==`, `===`

---

### **Clib.strncpy()**

---

SYNTAX: `Clib.strncpy(dstStr, srcStr, maxLen)`

WHERE: `dstStr` - destination string to which the source string will be

---

---

copied.

srcStr - source string to copy to destination string.

maxLen - maximum number of characters to copy.

RETURN: string - the value of dstStr after the copy process.

DESCRIPTION: This method copies:

```
Clib.min(Clib.strlen(srcStr)+1, MaxLen)
```

characters from srcStr to dstStr. If dstStr is not already defined then this method defines it as a string. The destination string is padded with `null` characters, if maxLen is greater than the length of srcStr, and a `null` character is appended to dstStr if maxLen characters are copied. It is safe to copy from one part of a string to another part of the same string. Returns the value of dstStr; that is, a variable into the destination array based at dstStr[0].

SEE: [Clib.strcpy\(\)](#)

---

### **Clib.strnicmp()**

---

SYNTAX: `Clib.strnicmp(str1, str2, maxLen)`

WHERE: str1 - first string to compare.

str2 - second string to compare

maxLen - maximum number of characters to use for comparison.

RETURN: number - negative, zero, or positive according to the following rules:

- `< 0` if str1 is less than str2
- `= 0` if str1 is the same as str2
- `> 0` if str1 is greater than str2

DESCRIPTION: This method compares up to maxLen bytes of str1 against str2 until there is a mismatch or the terminating `null` byte is reached. The comparison is case-insensitive. The comparison ends when maxLen bytes have been compared or when a terminating `null` byte has been compared, whichever comes first.

SEE: [Clib.strncmp\(\)](#), [Clib.strncmpi\(\)](#), `==`, `===`

---

### **Clib.strpbrk()**

---

SYNTAX: `Clib.strpbrk(str, chrSet)`

WHERE: str - string to be searched.

chrSet - set of characters to search for.

RETURN: string - beginning with the character in chrSet that was found, else `null`.

DESCRIPTION: This method searches str for any of the characters in chrSet, and returns the string based at the found character. Returns `null` if

---

---

no character from chrSet is found.

**Clib.strcspn()** returns a number and **Clib.strpbrk()** returns a string.

SEE: [Clib.strcspn\(\)](#)

EXAMPLE: `// See Clib.strcspn() for an example  
// using this function.`

---

## **Clib.strrchr()**

---

SYNTAX: `Clib.strrchr(str, chr)`

WHERE: `str` - string to search.

`chr` - character to search for.

RETURN: string - beginning with the first character found from the right, else `null`.

DESCRIPTION: This method searches a string for the last occurrence of `chr`. The search is in the reverse direction, from the right, for `chr` in a string. The method returns a variable indicating the last occurrence of `chr` in a string, else it returns `null` if `chr` is not found in `str`.

SEE: [Clib.strchr\(\)](#)

EXAMPLE: `// The following code:  
  
var str = "I can't stand soggy cereal."  
var substr = Clib.strrchr(str, 's');  
Clib.printf("str = %s\n", str);  
Screen.writeln("substr = " + substr);  
  
// Results in the following output.  
// str = I can't stand soggy cereal.  
// substr = soggy cereal.`

---

## **Clib.strspn()**

---

SYNTAX: `Clib.strspn(str, chrSet)`

WHERE: `str` - string to be searched.

`chrSet` - set of characters to search for.

RETURN: number - the offset or index into `str` of the first character that is not in `chrSet`.

DESCRIPTION: This method searches a string for any characters that are not in `chrSet`, and returns the offset of the first instance of such a character. If all characters in `str` are also in `chrSet`, the return is the length of string.

SEE: [Clib.strcspn\(\)](#)

---

## **Clib.strstr()**

---

SYNTAX: `Clib.strstr(srcStr, findStr)`

WHERE: `srcStr` - a string to search.

---

---

	<b>findStr</b> - a string to find.
RETURN:	string - beginning in srcStr with the first character in findStr that was found, else null.
DESCRIPTION:	This method searches srcStr, starting at srcStr[0], for the first occurrence of findStr. The search is case-sensitive. The method returns a variable indicating the beginning of the first occurrence of findStr in srcStr, else it returns null if findStr is not found in srcStr.
SEE:	<a href="#">Clib.strchr()</a> , <a href="#">Clib.strstri()</a>
EXAMPLE:	<pre>// The following code fragment:  function main() {     var Phrase = CString("To be or not to be? beep!");     do     {         Screen.writeln(Phrase);         Phrase = Clib.strstr(Phrase + 1, "be");     } while (Phrase != null); } // results in the following output. // To be or not to be? beep! // be or not to be? beep! // be? beep! // beep!</pre>

---

### **Clib.strstri()**

---

SYNTAX:	<b>Clib.strstri(srcStr, findStr)</b>
WHERE:	srcStr - a string to search.  findStr - a string to find.
RETURN:	string - beginning in srcStr with the first character in findStr that was found, else null.
DESCRIPTION:	This method searches srcStr, starting at srcStr[0], for the first occurrence of findStr. The search is case-insensitive. The method returns a variable indicating the beginning of the first occurrence of findStr in srcStr, else it returns null if findStr is not found in srcStr.
SEE:	<a href="#">Clib.strstr()</a>

---

### **Clib.strtod()**

---

SYNTAX:	<b>Clib.strtod(str[, endStr])</b>
WHERE:	str - string to be converted to a number.  endStr - the part of str after the characters that were actually parsed.
RETURN:	number - the first part of str converted to a double precision number.
DESCRIPTION:	This method converts the string str into a number and optionally

---

---

returns a partial string that begins beyond the characters parsed by this method. White space characters are skipped at the start of `str`, and the string characters are converted to a float as long as they match the following format.

`[sign][digits][.][digits][format[sign]digits]`

The parameter `endStr` is not compared against `null`, as it is in standard C implementations, and is optional. If the parameter `endStr` is supplied, then `endStr` is set to a string beginning at the first character that was not used in converting.

The return is the first part of `str`, converted to a floating-point number.

SEE: [Clib.strptime\(\)](#)

EXAMPLE: 

```
// The following strings, are examples
// that can be converted.
// "1"
// "1.8"
// "-400.456e-20"
// ".67e50"
// "2.5E+50"
```

---

## **Clib.strptime()**

---

SYNTAX: `Clib.strptime(srcStr, delimiterStr)`

WHERE: `srcStr` - source string consisting of delimited tokens.

`delimiterStr` - string of delimiter characters that separate tokens.

RETURN: string - a token, a substring, in `srcStr`, else `null` if there is not a token or if there are no more tokens.

DESCRIPTION: This method is unusual. The parameter `srcStr` is a string that consists of text tokens, substrings, separated by delimiter characters found in `delimiterStr`. The parameter `srcStr` may be altered during the first and subsequent calls to `Clib.strptime()`.

On the first call to `Clib.strptime()`, `srcStr` points to the string to tokenize and `delimiterStr` is a set of characters which are used to separate tokens in the source string. The first call, such as:

```
token = Clib.strptime(srcStr, delimiterStr)
```

returns a variable pointing to the `srcStr` array and based at the first character of the first token in `srcStr`. On subsequent calls, such as

```
token = Clib.strptime(null, delimiterStr)
```

the first argument is `null` and `Clib.strptime()` will continue through `srcStr` returning subsequent tokens.

The initial variable receiving tokens must remain valid throughout following calls that use `null`. If the variable is changed in any way, a subsequent use of `Clib.strptime()` must first use the syntax form in which the new string, not `null`, is

---

---

passed as a first parameter.

This method returns `null` if there are no more tokens; otherwise returns `srcStr` array variable based at the next token in `srcStr`.

SEE: [Clib.strstr\(\)](#)

EXAMPLE: 

```
// The following code:

var source =
    " Little   John,,,Eats ?? crackers;;;! ";
var token = Clib.strtok(source," , ");
while(null != token)
{
    Clib.puts(token);
    token = Clib.strtok(null,";? , ");
}

// produces the following list of tokens.
// Little
// John
// Eats
// crackers
// !
```

---

## **Clib.strtol()**

SYNTAX: `Clib.strtol(str[, endStr[, radix]])`

WHERE: `str` - string to be converted to a number.

`endStr` - the part of `str` after the characters that were actually parsed.

`radix` - the number base for the conversion.

RETURN: `number` - the first part of `str` converted to a long integer number.

DESCRIPTION: This method converts the string `str` into a number and optionally returns a string starting beyond the characters parsed in the method. White space characters are skipped at the start of `str`, and the string characters are converted to an integer as long as they match the following format.

`[sign][0][x][digits]`

The parameter `endStr` is not compared against `null`, as it is in standard C implementations and is optional. The parameter `radix` specifies the base for conversion. For example, base 10 would use decimal digits zero through nine, 0 - 9, and base 16 would use hexadecimal digits zero through nine, 0 - 9, uppercase letters "A" through "F", A - F, or lowercase letters "a" through "f", a - f. If `radix` is zero or is not supplied, then the radix is automatically determined based on the first characters of `str`.

If the parameter `endStr` is supplied, then `endStr` is set to a string beginning at the first character that was not used in converting. The return is the first part of `str`, converted to a floating-point number.

---

---

SEE: [Clib.strtod\(\)](#)

EXAMPLE: 

```
// As examples, the following strings//
// can be converted.
// "1"
// "12"
// "-400"
// "0xFACE"
```

---

### **Clib.strupr()**

---

SYNTAX: `Clib.strupr(str)`

WHERE: `str` - string in which to change case of characters to uppercase.

RETURN: string - the value of `str` after conversion of case.

DESCRIPTION: This method converts all lowercase letters in `str` to uppercase, starting at `str[0]` and ending before the terminating `null` byte. The return is the value of `str`, that is, a variable pointing to the start of `str` at `str[0]`.

SEE: [Clib.strlwr\(\)](#), [String.toUpperCase\(\)](#)

---

### **Clib.toascii()**

---

SYNTAX: `Clib.toascii(chr)`

WHERE: `chr` - character to be converted.

RETURN:

DESCRIPTION: This method translates `chr` to ASCII format, to seven bits. The translation is done by clearing all but the lowest 7 bits. The return is `chr` converted to ASCII. Remember that JavaScript has no true character type, thus, this method considers a single character string to be a `chr`.

SEE: [Clib.toascii\(\)](#), [Clib.tolower\(\)](#), [Clib.toupper\(\)](#), [String.toLowerCase\(\)](#), [String.toLowerCase\(\)](#), [String.invertCase\(\)](#)

---

### **Clib.tolower()**

---

SYNTAX: `Clib.tolower(chr)`

WHERE: `chr` - character to be converted.

RETURN:

DESCRIPTION: If `chr` is an uppercase alphabetic character, then this method returns `chr` converted to lowercase alphabetic, otherwise it returns `chr` unaltered. Remember that JavaScript has no true character type, thus, this method considers a single character string to be a `chr`.

SEE: [Clib.toascii\(\)](#), [Clib.tolower\(\)](#), [Clib.toupper\(\)](#), [String.toLowerCase\(\)](#), [String.toLowerCase\(\)](#), [String.invertCase\(\)](#)

---

### **Clib.toupper()**

---

SYNTAX: `Clib.toupper(chr)`

---

---

WHERE:	chr - character to be converted.
RETURN:	
DESCRIPTION:	If chr is a lowercase alphabetic character, then this method returns chr converted to uppercase alphabetic, otherwise it returns chr unaltered. Remember that JavaScript has no true character type, thus, this method considers a single character string to be a chr.
SEE:	<a href="#">Clib.toascii()</a> , <a href="#">Clib.tolower()</a> , <a href="#">Clib.toupper()</a> , <a href="#">String toLowerCase()</a> , <a href="#">String toLowerCase()</a> , <a href="#">String invertCase()</a>

---

### **Clib.vsprintf()**

---

SYNTAX:	<code>Clib.vsprintf(str, formatString, valist)</code>
WHERE:	str - to hold the formatted output.  formatString - string that specifies the final format.  valist - a variable list of arguments to be used according to formatString.
RETURN:	number - characters written to str, not including the terminating null character, on success, else EOF on error.
DESCRIPTION:	This method puts formatted output into str, a string, using a variable number of arguments, specified by valist. The parameter formatString specifies the format of the data put into the string. This method is similar to <a href="#">Clib.sprintf()</a> except that it takes a variable argument list.  The method returns the number of characters written to buffer, not including the terminating null byte, on success, else EOF on error.
SEE:	<a href="#">Clib.sprintf()</a> , <a href="#">Clib.va_start()</a>

---

## **Memory manipulation**

### **Clib.memchr()**

---

SYNTAX:	<code>Clib.memchr(buf, chr[, maxLen])</code>
WHERE:	buf - buffer or byte array to search.  chr - character to search for.  maxLen - maximum number of bytes to search.
RETURN:	buffer - beginning in array with the character found, else null if not found.
DESCRIPTION:	This method searches a buffer, a byte array, or a Blob, and returns a variable indicating or beginning with the first occurrence of chr. If the parameter maxLen is not specified, the method searches the entire array from element zero.
SEE:	<a href="#">Clib.strchr()</a>

---

## **Clib.memcmp()**

---

**SYNTAX:** `Clib.memcmp(buf1, buf2[, maxlen])`

**WHERE:** `buf1` - first buffer or byte array to use in comparison.  
`buf2` - second buffer or byte array to use in comparison.  
`maxLen` - maximum number of characters to compare.

**RETURN:** number - negative, zero, or positive according to the following rules:

- `< 0` if `str1` is less than `str2`
- `= 0` if `str1` is the same as `str2`
- `> 0` if `str1` is greater than `str2`

**DESCRIPTION:** This method compares the first `maxLen` bytes of `buf1` and `buf2`. If the parameter `maxLen` is not specified, then `maxLen` is the smaller of the lengths of `buf1` and `buf2`. If `maxLen` is specified and one of the arrays is shorter than the specified length, then ScriptEase treats length of the shorter array as being `maxLen`.

The example function checks to see if the shorter string is the same as the beginning of the longer string. This method differs from `Clib.strcmp()` in that this function returns `true` if passed the strings "foo" and "foobar", since it only compares characters up to the end of the shorter string.

**SEE:** [Clib.strcmp\(\)](#)

**EXAMPLE:**

```
function MyStrCmp(string1, string2)
{
    var len = Clib.min(string1.length,
                      string2.length);
    return(Clib.memcmp(string1, string2, len) == 0);
}
```

---

## **Clib.memcpy()**

---

**SYNTAX:** `Clib.memcpy(dstBuf, srcBuf[, maxlen])`

**WHERE:** `dstBuf` - destination buffer to which the source buffer will be copied.  
`srcBuf` - source buffer to copy to destination buffer.  
`maxLen` - maximum number of characters to copy.

**RETURN:** buffer - the final destination buffer.

**DESCRIPTION:** This method copies the number of bytes specified by `maxLen` from `srcBuf` to `dstBuf`. If `dstBuf` is not already defined, then it is defined as a buffer. If the parameter `maxLen` is not supplied, then all of the bytes in `srcBuf` are copied to `dstBuf`.

ScriptEase insures protection from data overwrite, so in ScriptEase the `Clib.memcpy()` method is the same as `Clib.memmove()`.

**SEE:** [Clib.strncpy\(\)](#), [Clib.memmove\(\)](#)

---

## **Clib.memmove()**

---

**SYNTAX:** `Clib.memmove(dstBuf, srcBuf[, maxlen])`  
**WHERE:** `dstBuf` - destination buffer to which the source buffer will be copied.  
  
`srcBuf` - source buffer to copy to destination buffer.  
`maxLen` - maximum number of characters to copy.  
**RETURN:** `buffer` - the final destination buffer.  
**DESCRIPTION:** This method copies the number of bytes specified by `maxLen` from `srcBuf` to `dstBuf`. If `dstBuf` is not already defined, then it is defined as a buffer. If the parameter `maxLen` is not supplied, then all of the bytes in `srcBuf` are copied to `dstBuf`.  
  
ScriptEase insures protection from data overwrite, so in ScriptEase the `Clib.memcpy()` method is the same as `Clib.memmove()`.  
**SEE:** [Clib.strncpy\(\)](#), [Clib.memcpy\(\)](#)

---

## **Clib.memset()**

---

**SYNTAX:** `Clib.memset(buf, chr[, maxlen])`  
**WHERE:** `buf` - a byte array or buffer.  
  
`chr` - character to set in `buf`.  
`maxLen` - number of bytes in `buf` to set to `chr`.  
**RETURN:** `buffer` - `buf` with the appropriate number of bytes set to `chr`.  
**DESCRIPTION:** This method sets the first number, as specified by `maxLen`, of bytes of `buf` to character `chr`. If `buf` is not already defined, then it is defined as a buffer of size `maxLen`. If the length of `buf` is less than the number of bytes specified by `maxLen`, then `buf` is grown to be big enough for `maxLen` bytes. If the parameter `maxLen` is not supplied, then `maxLen` is the size of `buf`, starting at index 0.  
**SEE:** [Clib.memchr\(\)](#)

---

## **Math**

### **Clib.abs()**

---

**SYNTAX:** `Clib.abs(x)`  
**WHERE:** `x` - number to work with.  
**RETURN:** `number` - absolute value of `x`.  
**DESCRIPTION:** This method returns the absolute, non-negative, value of `x`.  
**SEE:** [Clib.labs\(\)](#), [Clib.fabs\(\)](#)

---

### **Clib.acos()**

---

SYNTAX: `Clib.acos(x)`  
WHERE: `x` - number to work with.  
RETURN: number - arc cosine of `x`.  
DESCRIPTION: This method returns the arc cosine of `x` in the range of 0 to pi radians.  
SEE: [Clib.cos\(\)](#)

---

### **Clib.asin()**

---

SYNTAX: `Clib.asin(x)`  
WHERE: `x` - number to work with.  
RETURN: number - arc sine of `x`.  
DESCRIPTION: This method returns the arc sine of `x` in the range of -pi/2 to pi/2 radians.  
SEE: [Clib.sin\(\)](#)

---

### **Clib.atan()**

---

SYNTAX: `Clib.atan(x)`  
WHERE: `x` - number to work with.  
RETURN: number - arc tangent of `x`.  
DESCRIPTION: This method returns the arc tangent of `x` in the range of -pi/2 to pi/2 radians.  
SEE: [Clib.tan\(\)](#)

---

### **Clib.atan2()**

---

SYNTAX: `Clib.atan2(x, y)`  
WHERE: `x` - number to work with, numerator.  
`y` - number to work with, denominator.  
RETURN: number - arc tangent of `x/y`.  
DESCRIPTION: This method returns the arc tangent of `x/y`, in the range of -pi to +pi radians.  
SEE: [Clib.atan\(\)](#)

---

### **Clib.atof()**

---

SYNTAX: `Clib.atof(str)`  
WHERE: `str` - string to convert to a number.  
RETURN: number - `str` converted.  
DESCRIPTION: This method converts the ASCII string `str` to a floating-point value, if `str` can be converted.  
SEE: [Clib.atol\(\)](#)

---

---

### **Clib.atoi()**

SYNTAX: `Clib.atoi(str)`  
WHERE: `str` - string to convert to a number.  
RETURN: number - `str` converted.  
DESCRIPTION: This method converts the ASCII string `str` to an integer, if `str` can be converted.  
SEE: [Clib.atol\(\)](#)

---

---

### **Clib.atol()**

SYNTAX: `Clib.atol(str)`  
WHERE: `str` - string to convert to a number.  
RETURN: number - `str` converted.  
DESCRIPTION: This method converts the ASCII string `str` to a long integer, if `str` can be converted. This method is the same as the [Clib.atoi\(\)](#) method, since longs and integers are the same in ScriptEase.  
SEE: [Clib.atoi\(\)](#)

---

---

### **Clib.ceil()**

SYNTAX: `Clib.ceil(x)`  
WHERE: `x` - number to work with.  
RETURN: number - smallest integer greater than `x`.  
DESCRIPTION: This method returns the smallest integer value not less than `x`.  
SEE: [Clib.floor\(\)](#)

---

---

### **Clib.cos()**

SYNTAX: `Clib.cos(x)`  
WHERE: `x` - number to work with.  
RETURN: number - cosine of `x`.  
DESCRIPTION: This method returns the cosine of `x` in radians.  
SEE: [Clib.acos\(\)](#), [Clib.cosh\(\)](#)

---

---

### **Clib.cosh()**

SYNTAX: `Clib.cosh(x)`  
WHERE: `x` - number to work with.  
RETURN: number - hyperbolic cosine of `x`.  
DESCRIPTION: This method returns the hyperbolic cosine of `x`.  
SEE: [Clib.cos\(\)](#)

---

---

## **Clib.div()**

**SYNTAX:** `Clib.div(x, y)`  
**WHERE:** x - number to work with, numerator.  
y - number to work with, denominator.  
**RETURN:** object - a structure with the results of division in the following two properties:  

```
.quot    quotient  
.rem     remainder
```

  
**DESCRIPTION:** This method performs integer division and returns a quotient and remainder in an object, a structure. Since integers and long integers are the same in ScriptEase, `Clib.div()` is the same as `Clib.ldiv()`. The value returned is a structure with two elements or properties.  
**SEE:** [Clib.ldiv\(\)](#)

---

## **Clib.exp()**

**SYNTAX:** `Clib.exp(x)`  
**WHERE:** x - number to work with.  
**RETURN:** x - exponential value of x.  
**DESCRIPTION:** This method returns the exponential value of x.  
**SEE:** [Clib.frexp\(\)](#), [Clib.ldexp\(\)](#), [Clib.pow\(\)](#)

---

## **Clib.fabs()**

**SYNTAX:** `Clib.fabs(x)`  
**WHERE:** x - number to work with.  
**RETURN:** number - absolute value of x, a float.  
**DESCRIPTION:** This method returns the absolute, non-negative, value of a float x.  
**SEE:** [Clib.abs\(\)](#)

---

## **Clib.floor()**

**SYNTAX:** `Clib.floor(x)`  
**WHERE:** x - number to work with.  
**RETURN:** number - largest integer not greater than x.  
**DESCRIPTION:** This method returns the largest integer value not greater than x.  
**SEE:** [Clib.ceil\(\)](#)

---

## **Clib.fmod()**

**SYNTAX:** `Clib.fmod(x, y)`  
**WHERE:** x - number to work with, numerator.

---

---

	y - number to work with, denominator.
RETURN:	This method returns the remainder of x/y.
DESCRIPTION:	This method returns the remainder of x/y, that is, the modulus of two floats..
SEE:	<a href="#">Clib.modf()</a> , <a href="#">Clib.div()</a>
EXAMPLE:	

---

### **Clib.frexp()**

---

SYNTAX:	<code>Clib.frexp(x, exp)</code>
WHERE:	x - number to work with.  exp - exponent used with a mantissa.
RETURN:	number - mantissa with and absolute value between 0.5 and 1.0. If x is 0, return 0.
DESCRIPTION:	This method breaks x into a normalized mantissa between 0.5 and 1.0 and calculates an integer exponent of 2 such that $x == \text{mantissa} * 2^{\text{exponent}}$ . The return is normalized mantissa between 0.5 and 1.0, or 0. The exponent used is in x. See <a href="#">Clib.ldexp()</a> .
SEE:	<a href="#">Clib.exp()</a> , <a href="#">Clib.ldexp()</a> , <a href="#">Clib.pow()</a>

---

### **Clib.labs()**

---

SYNTAX:	<code>Clib.labs(x)</code>
WHERE:	x - number to work with.
RETURN:	number - absolute value of a long integer.
DESCRIPTION:	This method returns the absolute, non-negative, value of an integer.  Since integers and long integers are the same in ScriptEase, <code>Clib.labs()</code> is the same as <a href="#">Clib.abs()</a> .
SEE:	<a href="#">Clib.abs()</a> , <a href="#">Clib.fabs()</a>

---

### **Clib.ldexp()**

---

SYNTAX:	<code>Clib.ldexp(mantissa, exp)</code>
WHERE:	mantissa - mantissa to work with  exp - exponent used with a mantissa.
RETURN:	number - $\text{mantissa} * 2^{\text{exp}}$ .
DESCRIPTION:	This method is the inverse of <a href="#">Clib.frexp()</a> and calculates a floating point number using the following equation:  $\text{mantissa} * 2^{\text{exp}}$
SEE:	<a href="#">Clib.frexp()</a> , <a href="#">Clib.exp()</a>

---

---

## **Clib.ldiv()**

---

**SYNTAX:** `Clib.ldiv(x, y)`  
**WHERE:** x - number to work with, numerator.  
y - number to work with, denominator.  
**RETURN:** object - a structure with the results of division in the following two properties:  

```
    .quot    quotient  
    .rem     remainder
```

**DESCRIPTION:** This method performs integer division and returns a quotient and remainder in an object, a structure. Since integers and long integers are the same in ScriptEase, `Clib.div()` is the same as `Clib.ldiv()`. The value returned is a structure with two elements or properties.  
**SEE:** [Clib.div\(\)](#)

---

## **Clib.log()**

---

**SYNTAX:** `Clib.log(x)`  
**WHERE:** x - number to work with.  
**RETURN:** number - natural logarithm of x.  
**DESCRIPTION:** This method returns the natural logarithm of x.  
**SEE:** [Clib.exp\(\)](#), [Clib.log10\(\)](#), [Clib.pow\(\)](#)

---

## **Clib.log10()**

---

**SYNTAX:** `Clib.log10(x)`  
**WHERE:** x - number to work with.  
**RETURN:** number - base ten logarithm of x.  
**DESCRIPTION:** This method returns the base ten logarithm of x.  
**SEE:** [Clib.log\(\)](#)

---

## **Clib.max()**

---

**SYNTAX:** `Clib.max(x[, ...])`  
**WHERE:** x - number or list of numbers to work with.  
**RETURN:** number - maximum number passed.  
**DESCRIPTION:** This method is similar to the standard C macro, `max()`, with the differences that only one variable must be supplied and any number of other variables may be supplied for the comparison.  
**SEE:** [Clib.min\(\)](#)

---

## **Clib.min()**

---

**SYNTAX:** `Clib.min(x[, ...])`  
**WHERE:** x - number or list of numbers to work with.

---

---

RETURN: number - minimum number passed.

DESCRIPTION: This method is similar to the standard C macro, `min()`, with the differences that only one variable must be supplied and any number of other variables may be supplied for comparison.

SEE: [Clib.max\(\)](#)

---

### **Clib.modf()**

---

SYNTAX: `Clib.modf(x, i)`

WHERE: `x` - float to work with.

`i` - variable to receive the integral part of `x`.

RETURN: number - signed fractional part of `x`.

DESCRIPTION: This method splits a floating point number `x` into integer and fractional parts, where the integer and fraction both have the same sign as `x`. The method sets the parameter `i` to the integer part of `x` and returns the fractional part of `x`.

SEE: [Clib.fmod\(\)](#), [Clib.ldiv\(\)](#)

---

### **Clib.pow()**

---

SYNTAX: `Clib.pow(x, exp)`

WHERE: `x` - number to raise to a power.

`exp` - exponent of `x`, power to which to raise `x`.

RETURN: number -  $x^{\text{exp}}$ .

DESCRIPTION: This method returns `x` to the power of `y`.

SEE: [Clib.exp\(\)](#)

---

### **Clib.rand()**

---

SYNTAX: `Clib.rand()`

RETURN: number - random number between 0 and `RAND_MAX`, inclusive.

DESCRIPTION: This method returns pseudo-random number between 0 and `RAND_MAX`, inclusive. The sequence of pseudo-random numbers is affected by the initial generator seed and by earlier calls to `Clib.rand()`. See [Clib.srand\(\)](#) for information about the initial generator seed.

SEE: [Clib.srand\(\)](#), `RAND_MAX`

---

### **Clib.sin()**

---

SYNTAX: `Clib.sin(x)`

WHERE: `x` - number to work with.

RETURN: number - sine of `x`.

DESCRIPTION: This method returns the sine of `x` in radians.

---

---

SEE: [Clib.asin\(\)](#), [Clib.sinh\(\)](#)

---

### **Clib.sinh()**

SYNTAX: `Clib.sinh(x)`

WHERE: `x` - number to work with.

RETURN: number - hyperbolic sine of `x`.

DESCRIPTION: This method returns the hyperbolic sine of the float `x`.

SEE: [Clib.sin\(\)](#)

---

### **Clib.sqrt()**

SYNTAX: `Clib.sqrt(x)`

WHERE: `x` - number to work with.

RETURN: number - square root of `x`.

DESCRIPTION: This method returns the square root of `x`.

SEE: [Clib.exp\(\)](#), [Clib.pow\(\)](#)

---

### **Clib.srand()**

SYNTAX: `Clib.srand(seed)`

WHERE: `seed` - number with which to seed a random number generator.

RETURN: `void`.

DESCRIPTION: This method initializes a random number generator using the parameter `seed`. If `seed` is not supplied, then a random seed is generated in a manner that is specific to different operating systems. Use this method first when generating a sequence of random numbers.

SEE: [Clib.rand\(\)](#)

---

### **Clib.tan()**

SYNTAX: `Clib.tan(x)`

WHERE: `x` - number to work with.

RETURN: number - tangent of `x`.

DESCRIPTION: This method returns the tangent of `x` in radians.

SEE: [Clib.atan\(\)](#), [Clib.tanh\(\)](#)

---

### **Clib.tanh()**

SYNTAX: `Clib.tanh(x)`

WHERE: `x` - number to work with.

RETURN: number - hyperbolic tangent of `x`.

DESCRIPTION: This method calculates and returns the hyperbolic tangent of the

---

---

parameter x, a float.

SEE: [Clib.tan\(\)](#)

---

## Variable argument lists

### **Clib.va\_arg()**

---

SYNTAX: `Clib.va_arg([valist[, offset])`  
`Clib.va_arg(offset)`  
`Clib.va_arg()`

WHERE: `valist` - a variable list of arguments passed to a function.

`offset` - index of a particular argument.

RETURN: `value` - parameter being retrieved. If no parameters, the number of parameters.

DESCRIPTION: The method `Clib.va_arg()` provides an alternate way to retrieve a function's parameters. It's most often used when the number of parameters passed to the function is not constant. This method covers the same territory as the [Function property arguments\[\]](#) and is provided for those who prefer C functions for handling variable arguments.

When called with no parameters, it returns the number of parameters passed to the current function. If an offset is supplied, it returns the input variable at index: `offset`. `Clib.va_arg(0)` is the first parameter passed, `Clib.va_arg(1)` the second, etc. It is a fatal error to retrieve an argument offset beyond the number of parameters in the function or the `valist`.

The `valist` form, with an optional `offset`, uses a `valist` variable that has been previously initialized with [Clib.va\\_start\(\)](#). Each call to `Clib.va_arg(valist)` returns the next parameter passed to a function. If an `offset` is passed in the variable at that offset from the original starting place of the `valist` will be returned.

SEE: [Clib.va\\_start\(\)](#), [Clib.va\\_end\(\)](#), [Clib.vfprintf\(\)](#), [Clib.vfscanf\(\)](#), [Clib.vprintf\(\)](#), [Clib.vscanf\(\)](#), [Clib.vsprintf\(\)](#), [Clib.vsscanf\(\)](#)

EXAMPLE: `// The following script:`

```
function main()
{
    lips(0, 1, 2, 3, 4)
}

lips()
{
    Clib.va_start(valist)
    Clib.printf("va_arg(0) = %d\n", va_arg(0));
    Clib.printf("va_arg(1) = %d\n", va_arg(1));
    Clib.printf("va_arg(valist) = %d\n",
                va_arg(valist));
    Clib.printf("va_arg(valist, 2) = %d\n",
                va_arg(valist, 2));
    Clib.printf("va_arg(valist, 2) = %d\n",
```

---

---

```
        va_arg(valist, 2));
    Clib.printf("va_arg(valist) = %d\n",
               va_arg(valist));
    Clib.getch()
}

// produces the following output:
// va_arg(0) = 0
// va_arg(1) = 1
// va_arg(valist) = 0
// va_arg(valist, 2) = 3
// va_arg(valist, 2) = 3
// va_arg(valist) = 1
```

---

### **Clib.va\_end()**

---

**SYNTAX:** `Clib.va_end(valist)`

**WHERE:** `valist` - a variable list of arguments passed to a function.

**RETURN:** `void`.

**DESCRIPTION:** Terminates a variable arguments list. This method makes `valist` invalid. Many implementations of C require the calling of this function. ScriptEase does not. But, since people may expect it, ScriptEase provides it.

**SEE:** [Clib.va\\_arg\(\)](#), [Clib.va\\_start\(\)](#), [Clib.vfprintf\(\)](#), [Clib.vfscanf\(\)](#), [Clib.vprintf\(\)](#), [Clib.vscanf\(\)](#), [Clib.vsprintf\(\)](#), [Clib.vsscanf\(\)](#)

---

### **Clib.va\_start()**

---

**SYNTAX:** `Clib.va_start(valist[, inputVar])`

**WHERE:** `valist` - a variable list of arguments passed to a function.

**RETURN:** `number` - calls to `Clib.va_arg()`, that is, the number of variables in `valist`.

`inputVar` - an optional initial parameter for the variable parameter list.

**DESCRIPTION:** This method initializes `valist` for a function with a variable number of arguments. After the first call to this function, subsequent calls to `Clib.va_arg()` may be used to get the rest of the parameters in sequence.

The parameter `inputVar` must be one of the parameters defined on the function line of a function. The first argument returned by the first call to `Clib.va_arg()` will be the variable passed after `inputVar`. If `inputVar` is not provided, then the first parameter passed to a function will be the first one returned by `Clib.va_arg(valist)`.

**SEE:** [Clib.va\\_end\(\)](#), [Clib.va\\_start\(\)](#), [Clib.vfprintf\(\)](#), [Clib.vfscanf\(\)](#), [Clib.vprintf\(\)](#), [Clib.vscanf\(\)](#), [Clib.vsprintf\(\)](#), [Clib.vsscanf\(\)](#)

**EXAMPLE:**

```
// The following example uses and accepts
// a variable number of strings and
// concatenates them all together.
```

---

---

```
function MultiStrcat(Result, InitialString);
    // Append any number of strings to InitialString.
    // e.g., MultiStrcat(Result,
    // "C:\\", "FOO", ".", "CMD")
{
    Clib.strcpy(Result, ""); // initialize result;
    var Count = Clib.va_start(ArgList, InitialString);
    for (var i = 0; i < Count; i++)
        Result, va_arg(ArgList));
}
```

---

### **Clib.vfprintf()**

---

**SYNTAX:** `Clib.vfprintf(filePointer, formatString[,  
valist])`

**WHERE:** `filePointer` - pointer to file to use.

`formatString` - string that specifies the final format.

`valist` - a variable list of arguments to be formatted according to `formatString`.

**RETURN:** number - characters written, else a negative number on error.

**DESCRIPTION:** This method formats a string with a variable number of arguments and prints it to the file specified by `filePointer`. It returns the number of characters written, or a negative number if there was an output error.

**SEE:** [Clib.fprintf\(\)](#), [Clib.sprintf\(\)](#)

---

### **Clib.vfscanf()**

---

**SYNTAX:** `Clib.vfscanf(filePointer, formatString[,  
valist])`

**WHERE:** `filePointer` - pointer to file to use.

`formatString` - string that specifies the final format.

`valist` - a variable list of variables to hold data input according to `formatString`.

**RETURN:** number - input fields successfully scanned, converted, and stored, else EOF.

**DESCRIPTION:** This method is similar to `Clib.fscanf()` except that it takes a variable argument list. See [Clib.fscanf\(\)](#) for more details.

**SEE:** [Clib.va\\_arg\(\)](#), [Clib.fscanf\(\)](#)

---

### **Clib.vsscanf()**

---

**SYNTAX:** `Clib.vsscanf(str, formatString, valist)`

**WHERE:** `str` - string holding the data to read into variables according to `formatString`.

`formatString` - specifies how to read and store data in variables.

`valist` - a variable list of variables to hold data according to

---

---

	formatString.
RETURN:	number - input fields successfully scanned, converted, and stored, else EOF.
DESCRIPTION:	<p>This method is similar to <a href="#">Clib.sscanf()</a> except that it takes a variable argument list. The parameters following the format string will be assigned values according to the specifications of the format string.</p> <p>The function returns the number of input items assigned. This number may be fewer than the number of parameters requested if there was a matching failure.</p>
SEE:	<a href="#">Clib.va_arg()</a> , <a href="#">Clib.sscanf()</a>

# Date Object

ScriptEase shines in its ability to work with dates and provides two different systems for working with them. One is the standard Date object of JavaScript and the other is part of the Clib object which implements powerful routines from C. Two methods, `Date.fromSystem()` and `Date.toSystem()`, convert dates in the format of one system to the format of the other. The standard JavaScript Date object is described in this section.

To create a Date object which is set to the current date and time, use the new operator, as you would with any object.

```
var currentDate = new Date();
```

There are several ways to create a Date object which is set to a date and time. The following lines all demonstrate ways to get and set dates and times. See [Date\(\)](#) for a summary.

```
var aDate = new Date(milliseconds);
var bDate = new Date(datestring);
var cDate = new Date(year, month, day);
var dDate = new Date(year, month, day, hour, minute, second,
millisecond);
```

The first syntax returns a date and time represented by the number of milliseconds since midnight, January 1, 1970. This representation in milliseconds is a standard way of representing dates and times that makes it easy to calculate the amount of time between one date and another. Generally, you do not create dates in this way. Instead, you convert them to milliseconds format before doing calculations.

The second syntax accepts a string representing a date and optional time. The format of such a datestring is:

```
month day, year hours:minutes:seconds
```

For example, the following string:

```
"Friday 13, 1995 13:13:15"
```

specifies the date, Friday 13, 1995, and the time, one thirteen and 15 seconds p.m., which, expressed in 24 hour time, is 13:13 hours and 15 seconds. The time specification is optional and if included, the seconds specification is optional.

The third and fourth syntaxes are self-explanatory. All parameters passed to them are integers.

- **year**  
If a year is in the twentieth century, the 1900s, you need only supply the final two digits. Otherwise four digits must be supplied.
- **month**  
A month is specified as a number from 0 to 11. January is 0, and December is 11.
- **day**  
A day of the month is specified as a number from 1 to 31. The first day of a month is 1 and the last is 28, 29, 30, or 31.

- **hour**  
An hour is specified as a number from 0 to 23. Midnight is 0, and 11 p.m. is 23.
- **minute**  
A minute is specified as a number from 0 to 59. The first minute of an hour is 0, and the last is 59.
- **second**  
A second is specified as a number from 0 to 59. The first second of a minute is 0, and the last is 59.

For example, the following line of code:

```
var aDate = new Date(1492, 9, 12)
```

creates a Date object containing the date, October 12, 1492.

ScriptEase has a rich and full set of methods to work with dates and times. A programmer has a very complete set of tools to use when including date and time routines in a script. The **Clib object** also has methods for working with date and times that extend the power of ScriptEase beyond standard JavaScript.

The following list of methods has brief descriptions of the methods of the Date object. Instance methods are shown with a period, ".", in the SYNTAX: line. A specific instance of a variable should be put in front of the period to call a method. For example, the Date object aDate was created above, and, to call the **Date getDate()** method, the call would be: `aDate.getDate()`. Static methods have "Date." at their beginnings since these methods are called with literal calls, such as `Date.parse()`. These methods are part of the Date object itself instead of instances of the Date object.

## Date object instance methods

### Date()

---

SYNTAX:	<pre>new Date() new Date(milliseconds) new Date(string) new Date(year, month[, day[, hour[,         minute[, second[, millisecond]]]])</pre>
WHERE:	<p>milliseconds - number of milliseconds since midnight January 1, 1970 GMT, as returned by <b>Date.parse()</b>.</p> <p>string - a string with date information. The string should be in the following format: <code>Friday, October 31, 1998 15:30:00 GMT</code>, or a substring of this format. The string accepted by <code>Date()</code> is the same as for <b>Date.parse()</b>.</p> <p>year - four digit year, see <b>Date setYear()</b>. If year is passed alone, it is recognized as milliseconds.</p> <p>month - number, 0 - 11, month of year, see <b>Date setMonth()</b>.</p> <p>day - number, 1 - 31, day of month, see <b>Date setDate()</b>.</p> <p>hour - number, 0 - 24, hour of day, see <b>Date setHours()</b>.</p> <p>minute - number, 0 - 59, minute of hour, see <b>Date setMinutes()</b>.</p>

---

---

second - number, 0 - 59, second of minute, see [Date setSeconds\(\)](#).

millisecond - number, 0 - 999, millisecond of second, see [Date setMilliseconds\(\)](#).

RETURN: object - a Date object set according to the arguments passed. If no arguments are passed, then the current date and time are set.

DESCRIPTION: ScriptEase JavaScript has a rich set of methods for working with dates and times. The JavaScript Date object is a variable type that is different from the Clib date and time methods. The [Date.fromSystem\(\)](#) and [Date toSystem\(\)](#) methods allow conversion from and to the C style methods. See the [Date Object](#) for a complete description of the Date() function.

If the `new` operator is used, for example, `new Date(1999, 2)`, then a Date object is created using any parameters passed to the `Date()` constructor. However, if the `new` operator is not used, then all parameters are ignored and `Date()` returns a string representation of the current date and time, for example, "Wed Sep 4 11:54:16 2002".

SEE: [Date Object](#), [Date toSystem\(\)](#), [Date.fromSystem\(\)](#), [Date object instance methods](#), [Date object static methods](#), [Clib.time\(\)](#), [Clib.gmtime\(\)](#), [Clib.localtime\(\)](#), [Clib.mktime\(\)](#)

EXAMPLE:

```
var d = new Date() // date in a Date object
// d == Mon Aug 20 16:29:53 2001 // ie, current
// typeof(d) == object
// d._class == Date
var d = Date() // date as a String
// d == Mon Aug 20 16:29:53 2001 // ie, current
// typeof(d) == string
// d._class == String
var d = new Date().getDay()
// d == 1 // which is Monday
```

---

### **Date getDate()**

---

SYNTAX: `date.getDate()`

RETURN: number - a day of a month.

DESCRIPTION: This method returns the day of the month, as a number from 1 to 31, of a [Date object](#). The first day of a month is 1, and the last is 28, 29, 30, or 31.

---

### **Date getDay()**

---

SYNTAX: `date.getDay()`

RETURN: number - a day in a week.

DESCRIPTION: This method returns the day of the week, as a number from 0 to 6, of a [Date object](#). Sunday is 0, and Saturday is 6.

---

### **Date getFullYear()**

---

SYNTAX: `date.getFullYear()`  
RETURN: number - four digit year.  
DESCRIPTION: This method returns the year, as a number with four digits, of a **Date object**.

---

### **Date getHours()**

---

SYNTAX: `date.getHours()`  
RETURN: number - an hour in a day.  
DESCRIPTION: This method returns the hour, as a number from 0 to 23, of a **Date object**. Midnight is 0, and 11 p.m. is 23.

---

### **Date getMilliseconds()**

---

SYNTAX: `date.getMilliseconds()`  
RETURN: number - a millisecond in a second.  
DESCRIPTION: This method returns the millisecond, as a number from 0 to 999, of a **Date object**. The first millisecond in a second is 0, and the last is 999.

---

### **Date getMinutes()**

---

SYNTAX: `date.getMinutes()`  
RETURN: number - a minute in an hour.  
DESCRIPTION: This method returns the minute, as a number from 0 to 59, of a **Date object**. The first minute of an hour is 0, and the last is 59.

---

### **Date getMonth()**

---

SYNTAX: `date.getMonth()`  
RETURN: number - of a month in a year.  
DESCRIPTION: This method returns the month, as a number from 0 to 11, of a **Date object**. January is 0, and December is 11.

---

### **Date getSeconds()**

---

SYNTAX: `date.getSeconds()`  
RETURN: number - a second in a minute.  
DESCRIPTION: This method returns the second, as number from 0 to 59, of a **Date object**. The first second of a minute is 0, and the last is 59.

---

### **Date getTime()**

---

SYNTAX: `date.getTime()`  
RETURN: number - the milliseconds representation of a **Date object**.  
DESCRIPTION: Gets time information in the form of an integer representing the number of milliseconds from midnight on January 1, 1970,

---

---

GMT, to the date and time specified by a Date object.

---

### **Date getTimezoneOffset()**

---

SYNTAX: `date.getTimezoneOffset()`

RETURN: number - minutes.

DESCRIPTION: This method returns the difference, in minutes, between Greenwich Mean Time (GMT) and local time.

---

### **Date getUTCDate()**

---

SYNTAX: `date.getUTCDate()`

RETURN: number - a day of a month.

DESCRIPTION: This method returns the UTC day of the month, as a number from 1 to 31, of a **Date object**. The first day of a month is 1, and the last is 28, 29, 30, or 31.

---

### **Date getUTCDay()**

---

SYNTAX: `date.getUTCDay()`

RETURN: number - a day in a week.

DESCRIPTION: This method returns the day of the week, as a number from 0 to 6, of a **Date object**. Sunday is 0, and Saturday is 6.

---

### **Date getUTCFullYear()**

---

SYNTAX: `date.getUTCFullYear()`

RETURN: number - four digit year.

DESCRIPTION: This method returns the UTC year, as a number with four digits, of a **Date object**.

---

### **Date getUTCHours()**

---

SYNTAX: `date.getUTCHours()`

RETURN: number - an hour in a day.

DESCRIPTION: This method returns the UTC hour, as a number from 0 to 23, of a **Date object**. Midnight is 0, and 11 p.m. is 23.

---

### **Date getUTCMilliseconds()**

---

SYNTAX: `date.getUTCMilliseconds()`

RETURN: number - a millisecond in a second.

DESCRIPTION: This method returns the UTC millisecond, as a number from 0 to 999, of a **Date object**. The first millisecond in a second is 0, and the last is 999.

---

### **Date getUTCMinutes()**

---

SYNTAX: `date.getUTCMinutes()`  
RETURN: number - a minute in an hour.  
DESCRIPTION: This method returns the UTC minute, as a number from 0 to 59, of a **Date object**. The first minute of an hour is 0, and the last is 59.

---

### **Date getUTCMonth()**

---

SYNTAX: `date.getUTCMonth()`  
RETURN: number - of a month in a year.  
DESCRIPTION: number - of a month in a year.

---

### **Date getUTCSeconds()**

---

SYNTAX: `date.getUTCSeconds()`  
RETURN: number - a second in a minute.  
DESCRIPTION: This method returns the UTC second, as number from 0 to 59, of a **Date object**. The first second of a minute is 0, and the last is 59.

---

### **Date getYear()**

---

SYNTAX: `date.getYear()`  
RETURN: number - two digit year.  
DESCRIPTION: This method returns the year, as a number with two digits, of a **Date object**.

---

### **Date setDate()**

---

SYNTAX: `date.setDate(day)`  
WHERE: day - a day in a month.  
RETURN: number - time in milliseconds as set.  
DESCRIPTION: This method sets the day, as a number from 1 to 31, of a **Date object** to the parameter day. The first day of a month is 1, and the last is 28, 29, 30, or 31.

---

### **Date setFullYear()**

---

SYNTAX: `date.setFullYear(year[, month[, date]])`  
WHERE: year - a four digit year.  
month - a month in a year.  
day - a day in a month.  
RETURN: number - time in milliseconds as set.  
DESCRIPTION: This method sets the year of a **Date object** to the parameter year. The parameter year is expressed with four digits.  
The parameter month is the same as for **Date setMonth()**.

---

---

The parameter day is the same as for [Date setDate\(\)](#).

---

### **Date setHours()**

---

**SYNTAX:** `Date.setHours(hour[, minute[, second[, millisecond]])`

**WHERE:** hour - an hour in a day.  
minute - a minute in an hour.  
second - a second in a minute.  
millisecond - a millisecond in a second.

**RETURN:** number - time in milliseconds as set.

**DESCRIPTION:** This method sets the hour, as a number from 0 to 23, of a [Date object](#) to the parameter hours. Midnight is 0, and 11 p.m. is 23.  
The parameter minute is the same as for [Date setMinutes\(\)](#).  
The parameter second is the same as for [Date setSeconds\(\)](#).  
The parameter milliseconds is the same as for [Date setMilliseconds\(\)](#).

---

### **Date setMilliseconds()**

---

**SYNTAX:** `date.setMilliseconds(millisecond)`

**WHERE:** millisecond - a millisecond in a minute.

**RETURN:** number - time in milliseconds as set.

**DESCRIPTION:** This method sets the millisecond, as a number from 0 to 59, of a [Date object](#) to the parameter millisecond. The first millisecond in a second is 0, and the last is 999.

---

### **Date setMinutes()**

---

**SYNTAX:** `date.setMinutes(minute[, second[, millisecond]])`

**WHERE:** minute - a minute in an hour.  
second - a second in a minute.  
millisecond - a millisecond in a second.

**RETURN:** number - time in milliseconds.

**DESCRIPTION:** This method sets the minute, as a number from 0 to 59, of a [Date object](#) to the parameter minute. The first minute of an hour is 0, and the last is 59.  
The parameter second is the same as for [Date setSeconds\(\)](#).  
The parameter milliseconds is the same as for [Date setMilliseconds\(\)](#).

---

### **Date setMonth()**

---

**SYNTAX:** `Date.setMonth(month[, day])`

---

---

WHERE:	month - a month in a year. day - a day in a month.
RETURN:	number - time in milliseconds.
DESCRIPTION:	This method sets the month, as a number from 0 to 11, of a <b>Date object</b> to the parameter month. January is 0, and December is 11. The parameter day is the same as for <b>Date setDate()</b> .

---

### **Date setSeconds()**

---

SYNTAX:	<code>date.setSeconds(second[, millisecond])</code>
WHERE:	second - a second in a minute. millisecond - a millisecond in a second.
RETURN:	number - time in milliseconds.
DESCRIPTION:	This method sets the second, as a number from 0 to 59, of a <b>Date object</b> to the parameter second. The first second of a minute is 0, and the last is 59. The parameter milliseconds is the same as for <b>Date setMilliseconds()</b> .

---

### **Date setTime()**

---

SYNTAX:	<code>date.setTime(millisecond)</code>
WHERE:	millisecond - the time in milliseconds.
RETURN:	number - time in milliseconds as set.
DESCRIPTION:	This method sets a <b>Date object</b> to the date and time specified by the parameter milliseconds which is the number of milliseconds from midnight on January 1, 1970, GMT.

---

### **Date setUTCDate()**

---

SYNTAX:	<code>date.setUTCDate(day)</code>
WHERE:	day - a day in a month.
RETURN:	number - time in milliseconds as set.
DESCRIPTION:	This method sets the UTC day, as a number from 1 to 31, of a <b>Date object</b> to the parameter day. The first day of a month is 1, and the last is 28, 29, 30, or 31.

---

### **Date setUTCFullYear()**

---

SYNTAX:	<code>date.setUTCFullYear(year[, month[, date]])</code>
WHERE:	year - a four digit year. month - a month in a year. day - a day in a month.

---

---

RETURN:	number - time in milliseconds as set.
DESCRIPTION:	This method sets the UTC year of a <b>Date object</b> to the parameter year. The parameter year is expressed with four digits. The parameter month is the same as for <b>Date setUTCMonth()</b> . The parameter day is the same as for <b>Date setUTCDate()</b> .

---

### **Date setUTCHours()**

---

SYNTAX:	<code>Date.setUTCHours(hour[, minute[, second[, millisecond]])</code>
WHERE:	hour - an hour in a day. minute - a minute in an hour. second - a second in a minute. millisecond - a millisecond in a second.
RETURN:	number - time in milliseconds as set.
DESCRIPTION:	This method sets the UTC hour, as a number from 0 to 23, of a <b>Date object</b> to the parameter hours. Midnight is 0, and 11 p.m. is 23. The parameter minute is the same as for <b>Date setUTCMinutes()</b> . The parameter second is the same as for <b>Date setUTCSeconds()</b> . The parameter milliseconds is the same as for <b>Date setUTCMilliseconds()</b> .

---

### **Date setUTCMilliseconds()**

---

SYNTAX:	<code>date.setUTCMilliseconds(millisecond)</code>
WHERE:	millisecond - a millisecond in a minute.
RETURN:	number - time in milliseconds as set.
DESCRIPTION:	This method sets the UTC millisecond, as a number from 0 to 59, of a <b>Date object</b> to the parameter millisecond. The first millisecond in a second is 0, and the last is 999.

---

### **Date setUTCMinutes()**

---

SYNTAX:	<code>date.setUTCMinutes(minute[, second[, millisecond]])</code>
WHERE:	minute - a minute in an hour. second - a second in a minute. millisecond - a millisecond in a second.
RETURN:	number - time in milliseconds.
DESCRIPTION:	This method sets the UTC minute, as a number from 0 to 59, of a <b>Date object</b> to the parameter minute. The first minute of an hour is 0, and the last is 59.

---

---

The parameter second is the same as for [Date setUTCSeconds\(\)](#).

The parameter milliseconds is the same as for [Date setUTCMilliseconds\(\)](#).

---

### **Date setUTCMonth()**

---

SYNTAX: `Date.setUTCMonth(month[, day])`

WHERE: month - a month in a year.

day - a day in a month.

RETURN: number - time in milliseconds.

DESCRIPTION: This method sets the UTC month, as a number from 0 to 11, of a [Date object](#) to the parameter month. January is 0, and December is 11.

The parameter day is the same as for [Date setUTCDate\(\)](#).

---

### **Date setUTCSeconds()**

---

SYNTAX: `date.setUTCSeconds(second[, millisecond])`

WHERE: second - a second in a minute.

millisecond - a millisecond in a second.

RETURN: number - time in milliseconds.

DESCRIPTION: This method sets the UTC second, as a number from 0 to 59, of a [Date object](#) to the parameter second. The first second of a minute is 0, and the last is 59.

The parameter milliseconds is the same as for [Date setUTCMilliseconds\(\)](#).

---

### **Date setYear()**

---

SYNTAX: `date.setYear(year)`

WHERE: year - four digit year, unless in the 1900s in which case it may be a two digit year.

RETURN: number - time in milliseconds as set.

DESCRIPTION: This method sets the year of a [Date object](#) to the parameter year. The parameter year may be expressed with two digits for a year in the twentieth century, the 1900s. Four digits are necessary for any other century.

---

### **Date toDateString()**

---

SYNTAX: `date.toDateString()`

RETURN: string - representation of the date portion of the current object.

DESCRIPTION: Returns the Date portion of the current date as a string. This string is formatted to read "Month Day, Year", for example, "May 1, 2000". This method uses the local time, not UTC time.

---

---

SEE: [Date toString\(\)](#), [Date toTimeString\(\)](#), [Date toLocaleDateString\(\)](#)

EXAMPLE: 

```
var d = new Date();
var s = d.toDateString();
```

---

### **Date toGMTString()**

---

SYNTAX: `date.toGMTString()`

RETURN: string - string representation of the GMT date and time.

DESCRIPTION: This method converts a **Date object** to a string, based on Greenwich Mean Time.

EXAMPLE: 

```
var d = new Date();
Screen.writeln(d.toGMTString());

// The fragment above would produce something like:
// Mon May 1 15:48:38 2000 GMT
```

---

### **Date toLocaleDateString()**

---

SYNTAX: `date.toLocaleDateString()`

RETURN: string - locale-sensitive string representation of the date portion of the current date.

DESCRIPTION: This function behaves in exactly the same manner as **Date toDateString()**. This function is designed to take in the current locale when formatting the string. Locale reflects the time zone of a user.

SEE: [Date toString\(\)](#), [Date toLocaleTimeString\(\)](#), [Date toLocaleString\(\)](#)

EXAMPLE: 

```
var d = new Date();
var s = d.toLocaleDateString();
```

---

### **Date toLocaleString()**

---

SYNTAX: `date.toLocaleString()`

RETURN: string - locale-sensitive string representation of the current date.

DESCRIPTION: This function behaves in exactly the same manner as **Date toString()**. This function is designed to take in the current locale when formatting the string, though this functionality is currently unimplemented. Locale reflects the time zone of a user.

SEE: [Date toString\(\)](#), [Date toLocaleTimeString\(\)](#), [Date toLocaleDateString\(\)](#)

EXAMPLE: 

```
var d = new Date();
var s = d.toLocaleString();
```

---

### **Date toLocaleTimeString()**

---

SYNTAX: `date.toLocaleTimeString()`

RETURN: string - locale-sensitive string representation of the time portion of the current date.

DESCRIPTION: This function behaves in exactly the same manner as **Date toTimeString()**. This function is designed to take in the current

---

---

locale when formatting the string. Locale reflects the time zone of a user.

---

### **Date toString()**

---

SYNTAX: `date.toString()`

RETURN: string - representation of the date and time data in a **Date object**.

DESCRIPTION: Converts the date and time information in a Date object to a string in a form such as: "Mon May 1 09:24:38 2000"

SEE: [Date toDateString\(\)](#), [Date toLocaleString\(\)](#), [Date toTimeString\(\)](#)

EXAMPLE: 

```
var d = new Date();
var s = d.toString();
```

---

### **Date toSystem()**

---

SYNTAX: `date.toSystem()`

RETURN: number - the **Date object** date and time value converted to the system date and time.

DESCRIPTION: This method converts a Date object to a system time format which is the same as that returned by the **Clib.time()** method. To create a Date object from a variable in system time format, see the **Date.fromSystem()** method.

---

### **Date toTimeString()**

---

SYNTAX: `date.toTimeString()`

RETURN: string - representation of the Time portion of the current object.

DESCRIPTION: This function returns the time portion of the current date as a string. This string is formatted to read "Hours:Minutes:Seconds", as in "16:43:23". This function uses the local time, rather than the UTC time.

SEE: [Date toString\(\)](#), [Date toDateString\(\)](#), [Date toLocaleDateString\(\)](#)

EXAMPLE: 

```
var d = new Date();
var s = d.toTimeString();
```

---

### **Date toUTCString()**

---

SYNTAX: `date.toUTCString()`

RETURN: string - representation of the UTC date and time data in a **Date object**.

DESCRIPTION: Converts the UTC date and time information in a Date object to a string in a form such as: "Mon May 1 09:24:38 2000"

SEE: [Date toDateString\(\)](#), [Date toLocaleString\(\)](#), [Date toTimeString\(\)](#)

EXAMPLE: 

```
var d = new Date();
var s = d.toString();
```

---

### **Date valueOf()**

---

SYNTAX: `date.valueOf()`

---

---

RETURN:	number - the value of the date and time information in a Date object.
DESCRIPTION:	The numeric representation of a <b>Date object</b> .
SEE:	<a href="#">Date toString()</a>

---

## Date object static methods

The **Date object** has three special methods that are called from the object itself, rather than from an instance of it: **Date.fromSystem()**, **Date.parse()**, and **Date.UTC()**.

### Date.fromSystem()

---

SYNTAX:	<code>Date.fromSystem(time)</code>
WHERE:	time - time in system data format, the same format as returned by <b>Clib.time()</b>
RETURN:	object - Date object with the time passed.
DESCRIPTION:	This method converts the parameter time, which is in the same format as returned by the <code>Clib.time()</code> , to a standard JavaScript <b>Date object</b> .
EXAMPLE:	<pre>// To create a Date object // from date information obtained using // Clib, use code similar to:  var SysDate = Clib.time(); var ObjDate = Date.fromSystem(SysDate);  // To convert a Date object to system format // that can be used by // the methods of the Clib object, // use code similar to:  var SysDate = ObjDate.toSystem();</pre>

---

### Date.parse()

---

SYNTAX:	<code>Date.parse(datestring)</code>
WHERE:	datestring - A string representing the date and time to be passed
RETURN:	number - milliseconds between the datestring and midnight, January 1, 1970 GMT.
DESCRIPTION:	This method converts the string datestring to a <b>Date object</b> . The string should be in the following format: <code>Friday, October 31, 1998 15:30:00</code> , or a substring of this format. The full format is returned by the <b>Date toGMTString()</b> method, by email and by Internet applications. The day of the week, time zone, time specification or seconds field may be omitted.
SEE:	<a href="#">Date object</a> , <a href="#">Date setTime()</a> , <a href="#">Date toGMTString()</a> , <a href="#">Date.UTC</a>
EXAMPLE:	<pre>//The following code sets the date to March 2, 1992 var theDate = Date.parse("March 2, 1992") //Note: var theDate = Date.parse(datestring);</pre>

---

---

```
//is equivalent to:
var theDate = new Date(datestring);
// The following are valid, but not exhaustive
var ms;
ms = Date.parse(new Date().toGMTString());
ms = Date.parse("Mon Aug 20 14:41:01 2001 GMT");
ms = Date.parse("Mon Aug 20 14:41:01 2001");
ms = Date.parse("Mon Aug 20 14:41:01 2001");
ms = Date.parse("August 20 09:35:50 2001");
ms = Date.parse("Aug 20 09:35:50 2001");
ms = Date.parse("August 20, 2001");
ms = Date.parse("August 20 2001");
ms = Date.parse("Aug 20, 2001");
ms = Date.parse("Aug 20 2001");
```

---

## Date.UTC()

**SYNTAX:** `Date.UTC(year, month, day[, hours[, minutes[, seconds[, milliseconds]]]])`

**WHERE:**

- year** - A year, represented in four or two-digit format after 1900.  
NOTE: For year 2000 compliance, this year **MUST** be represented in four-digit format
- month** - A number between 0 (January) and 11 (December) representing the month
- day** - A number between 1 and 31 representing the day of the month. Note that `Month` uses 1 as its lowest value whereas many other arguments use 0
- hours** - A number between 0 (midnight) and 23 (11 PM) representing the hours
- minutes** - A number between 0 (one minute) and 59 (59 minutes) representing the minutes. This is an optional argument which may be omitted if `Seconds` and `Minutes` are omitted as well.
- seconds** - A number between 0 and 59 representing the seconds. This parameter is optional.
- milliseconds** - A number between 0 and 999 which represents the milliseconds. This is an optional parameter.

**RETURN:** number - milliseconds from midnight, January 1, 1970, to the date and time specified.

**DESCRIPTION:** The method interprets its parameters as a date. The parameters are interpreted as referring to Greenwich Mean Time (GMT).

**SEE:** [Date object](#), [Date.parse\(\)](#), [Date setTime\(\)](#)

**EXAMPLE:**

```
// The following code creates a Date object
// using UTC time:
foo = new Date(Date.UTC(1998, 3, 9, 1, 0, 0, 8))
```

---

---

# Dos Object

platform: DOS, Win16

The methods in this section are specific to the DOS or WIN16 versions of ScriptEase. Most of these routines allow a programmer to have more power than is generally acknowledged as safe under the scripting guidelines of general ScriptEase. Be cautious when you use these commands. They allow much latitude in what may be done at a very low programming level with little or no built-in protections.

The methods in this section are preceded with the Object name Dos, since individual instances of the Dos Object are not created. In other words, the Dos object has only static methods. For example, `Dos.inport(portid)` is the syntax to use to read a byte from a hardware port. Remember to prepend "Dos." to the method names as shown in this section.

## Dos object static methods

---

### Dos.address()

**SYNTAX:** `Dos.address(segment, offset)`  
**WHERE:** `segment` - segment portion of memory address.  
`offset` - offset portion of memory address.  
**RETURN:** number - memory address, a segment:offset address suitable for use in calls such as `SElib.peek()` and `SElib.poke()`.  
**DESCRIPTION:** Convert segment:offset pointer into memory address.  
**SEE:** [Dos.offset\(\)](#), [Dos.segment\(\)](#)

---

### Dos.asm()

**SYNTAX:** `Dos.asm(buf[, ax[, bx[, cx[, dx[, si[, di[, ds[, es]]]]]]])`  
**WHERE:** `buf` - a byte buffer.  
`ax, bx, cx, dx, si, di, ds, es` - registers.  
**RETURN:** number - long value for whatever is in DX:AX when `buf` returns.  
**DESCRIPTION:** Make a far call to the routine that you have coded into `buf`. `ax, bx, cx, dx, si, di, ds, and es` are optional; if some or all are supplied, then the `ax, bx, cx, etc...` will be set to these values when the code at `buf` is called. The code in `buf` will be executed with a far call to that address, and is responsible for returning via `retf` or other means. The ScriptEase calling code will restore ALL registers except `ss, sp, ax, bx, cx, and dx`. If `es` or `ds` are supplied, then they must be valid values or 0, if 0 then the current value will be used.  
**EXAMPLE:**

```
// The following example uses 80x86 assembly code
// to rotate memory bits:

// return value of byte b rotate count byte
```

---

---

```
function RotateByteRight(b, count)
{
    assert( 0 <= b && b <= 0xFF );
    assert( 0 <= count && count <= 8 );
    return asm( '\xD2\xC8\xCB', b, 0, count, 0 );

    // assembly code for would look as follows:
    //  ror al, cl D2C8
    //  retf CB
}
```

---

### **Dos.inport()**

---

**SYNTAX:** `Dos.inport(portid)`  
**WHERE:** portid - port from which to read.  
**RETURN:** number - byte of data from a hardware port.  
**DESCRIPTION:** Read byte from a hardware port: portid.  
**SEE:** [Dos.inportw\(\)](#)

---

### **Dos.inportw()**

---

**SYNTAX:** `Dos.inportw(portid)`  
**WHERE:** portid - port from which to read.  
**RETURN:** number - 16 bit word of data from a hardware port.  
**DESCRIPTION:** Read a word (16 bit) from hardware port: portid. Value read is unsigned (not negative).  
**SEE:** [Dos.inport\(\)](#)

---

### **Dos.interrupt()**

---

**SYNTAX:** `Dos.interrupt(interrupt, regIn[, regOut])`  
**WHERE:** interrupt - DOS interrupt number.

regIn - an object/structure with properties/elements that correspond to the registers of an 8086 processor. The registers will be set to these values when the method is called.

regOut - an object/structure with properties/elements that will be set to the corresponding registers of the processor when the function is exited.

**RETURN:** boolean - since many interrupts set the carry flag for error, this function returns `false` if the carry flag is set, else `true`.

**DESCRIPTION:** Executes an 8086 interrupt. Set registers, call 8086 interrupt function, and then get the return values of the registers. The parameters regIn and regOut are structures containing the elements corresponding to the registers on an 8086. On input, those structure members that are defined will be set, and those that are not defined will be set to zero, with the exception of the segment registers (es and ds) which retain their current values if not explicitly specified. The possible defined input values are ax,

---

---

ah, al, bx, bh, bl, cx, ch, cl, dx, dh, dl, bp, si, di, ds, and es. All Fields of the output reg structure are the same, with the addition of the *FLAGS* member, and all are set before returning. If regOut is not supplied, then the return registers and *FLAGS* register will be set for regIn on return from the interrupt call.

The parameter regOut is set to the register values upon return from Interrupt. If regOut is not supplied then regIn is set to contain the register values upon return from Interrupt.

```
EXAMPLE: // The following example calls the DOS interrupt
// service 0x2C to read the clock:

// display DOS time as accurately as it is read
PrintDOStime()
{
    reg.ah = 0x2C;
    interrupt(0x21, reg);
    printf("%2d:%02d:%02d", reg.ch, reg.cl, reg.dh);
}
```

---

### **Dos.offset()**

---

SYNTAX: `Dos.offset(buf)`  
`Dos.offset(address)`

WHERE: `buf` - a byte buffer.

`address` - address in memory.

RETURN: number - offset of buffer such that 8086 would recognize the address segment::buffer as pointing to the first byte of buf.

DESCRIPTION: **Dos.segment()** and `Dos.offset()` return the segment and offset of the data at index 0 of buf, which must be a byte array. The buffer must be big enough for whatever purpose it is used, and no changes may be made to the size of buf after these values are determined since changing the size of buf might change its absolute address. If the address versions are used, then address is assumed to be a far pointer to data, and segment will be the high word while address will be the low word. See **Dos.address()** for converting segment and offset into a single address.

SEE: [Dos.offset\(\)](#), [Dos.address\(\)](#)

---

### **Dos.output()**

---

SYNTAX: `Dos.output(portid, value)`

WHERE: `portid` - port to which to send value.

`value` - a byte of data to send to the port identified by portid.

RETURN: void.

DESCRIPTION: Write a byte value to hardware port: portid.

---

### **Dos.outputw()**

---

SYNTAX: `Dos.outputw(portid, value)`

---

---

WHERE:	portid - port to which to send value. value - a 16-bit word of data to send to the port identified by portid.
RETURN:	void.
DESCRIPTION:	Write a 16-bit word value to hardware port: portid.

---

### **Dos.segment()**

---

SYNTAX:	Dos.segment(buf) Dos.segment(address)
WHERE:	buf - a byte buffer. address - address in memory.
RETURN:	number - segment of buffer such that 8086 would recognize the address segment::buffer as pointing to the first byte of buf.
DESCRIPTION:	Dos.segment() and <b>Dos.offset()</b> return the segment and offset of the data at index 0 of buf, which must be a byte array. The buffer must be big enough for whatever purpose it is used, and no changes may be made to the size of buf after these values are determined since changing the size of buf might change its absolute address. If the address versions are used, then address is assumed to be a far pointer to data, and segment will be the high word while address will be the low word. See <b>Dos.address()</b> for converting segment and offset into a single address.

# Function Object

The Function object is one of three ways to define and use objects in ScriptEase. The three ways to work with objects are:

- Use the function keyword and define a function in a normal way:  
`function myFunc(x) {return x + 4;}`
- Construct a new Function object:  
`var myFunc = new Function("x", "return x + 4;");`
- Define and assign a function literal:  
`var myFunc = function(x) {return x + 4;}`

All three of these ways of defining and using functions produce the same result,  $x + 4$ . The differences are in definition and use of functions. Each way has a strength that is very powerful in some circumstances, power that allows elegance in programming. The methods and discussion in this segment on the Function object deal with the second way shown above, the construction of a new Function object.

## Function object instance methods

### Function()

---

SYNTAX: `new Function(params[, ...], body)`

WHERE: `params` - one or a list of parameters for the function.

`body` - the body of the function as a string.

RETURN: `object` - a new function object with the specified parameters and body that can later be executed just like any other function.

DESCRIPTION: The parameters passed to the function can be in one of two formats. All parameters are strings representing parameter names, although multiple parameter names can be grouped together with commas. These two options can be combined as well. For example, `new Function("a", "b", "c", "return")` is the same as `new Function("a, b", "c", "return")`. The body of the function is parsed just as any other function would be. If there is an error parsing either the parameter list or the function body, a runtime error is generated. If this function is later called as a constructor, then a new object is created whose internal `_prototype` property is equal to the `prototype` property of the new function object. Note that this function can also be called directly, without the *new* operator.

EXAMPLE: 

```
// The following will create a new Function object
// and provide some properties
// through the prototype property.

var myFunction = new Function("a", "b",
    "this.value = a + b");
var printFunction = new Function
    ("Screen.writeln(this.value)");
myFunction.prototype.print = printFunction;
```

---

---

```
var foo = new myFunction( 4, 5 );
foo.print();

// This code will print out the value "9",
// which was the value stored in foo when it was
// created with the myFunction constructor.
```

---

## Function apply()

---

**SYNTAX:** `function.apply([thisObj[, arguments]])`  
**WHERE:** `thisObj` - object that will be used as the "this" variable while calling this function. If this is not supplied, then the global object is used instead.

`arguments` - array of arguments to pass to the function as an Array object or a list in the form of `[arg1, arg2[, ...]]`. The brackets "[]" around a list of arguments are required. Note that the similar method **Function call()** can receive the same arguments as a list. Compare the following ways of passing arguments:

```
// Uses an Array object
function.apply(this, argArray)
// Uses brackets
function.apply(this, [arg1, arg2])
// Uses argument list
function.call(this, arg1, arg2)
```

**RETURN:** variable - the result of calling the function object with the specified "this" variable and arguments.

**DESCRIPTION:** This method is similar to calling the function directly, only the user is able to pass a variable to use as the "this" variable, and the arguments to the function are passed as an array. If `arguments` is not supplied, then no arguments are passed to the function. If the `arguments` parameter is not a valid Array object or list of arguments inside of brackets "[]", then a runtime error is generated.

**SEE:** [Function\(\)](#), [Function call\(\)](#)

**EXAMPLE:**

```
var myFunction = new Function("a,b","return a + b");
var args = new Array(4,5);
myFunction.apply(global, args);
//or
myFunction.apply(global, [4,5]);

// This code sample will return 9, which is
// the result of calling myFunction with
// the arguments 4 and 5, from the args array.
```

---

## Function call()

---

**SYNTAX:** `function.call([thisObj[, arguments[, ...]]])`  
**WHERE:** `thisObj` - An object that will be used as the "this" variable while calling this function. If this is not supplied, then the global object is used instead.

`arguments` - list of arguments to pass to the function. Note that

---

---

the similar method **Function apply()** can receive the same arguments as an array. Compare the following ways of passing arguments:

```
// Uses an Array object
function.apply(this, argArray)
// Uses brackets
function.apply(this, [arg1, arg2])
// Uses argument list
function.call(this, arg1, arg2)
```

**RETURN:** variable - the result of calling the function object with the specified "this" variable and arguments.

**DESCRIPTION:** This method is almost identical to calling the function directly, only the user is able to supply the "this" variable that the function will use. Otherwise, it is the same.

**SEE:** [Function\(\)](#), [Function.apply\(\)](#)

**EXAMPLE:**

```
// The following code:

var myFunction = new Function("arg",
                             "return this.a + arg");
var obj = { a:4 };
myFunction.call( obj, 5 );

// This code fragment returns the value 9,
// which is the result of fetching this.a
// from the current object (which is obj) and
// adding the first parameter passed, which is 5.
```

---

## **Function toString()**

---

**SYNTAX:** `function.toString()`

**RETURN:** string - a representation of the function.

**DESCRIPTION:** This method attempts to generate the same code that built the function. Any spacing, semicolons, newlines, etc., are implementation-dependent. This method tries to make the output as human-readable as possible. Note that the function name is always "anonymous", because the function itself is unnamed, even though the function object has a name. Also, note that this function is very rarely called directly, rather it is called implicitly through conversions such as **global.ToString()**.

**EXAMPLE:**

```
var myFunction = new Function("a", "b",
                              "this.value = a + b");
Screen.writeln( myFunction );

// This fragment will print the following
// to the screen:

function anonymous(a, b)
{
    this .value = a + b
}
```

---

---

# Math Object

The Math object in ScriptEase has a full and powerful set of methods and properties for mathematical operations. A programmer has a rich set of mathematical tools for the task of doing mathematical calculations in a script.

The methods in this section are preceded with the Object name Math, since individual instances of the Math Object are not created. For example, `Math.abs()` is the syntax to use to get the absolute value of a number.

## Math object static properties

### Math.E

---

**SYNTAX:** `Math.E`  
**DESCRIPTION:** The number value for e, the base of natural logarithms. This value is represented internally as approximately 2.7182818284590452354.  
**EXAMPLE:** `var n = Math.E;`

---

### Math.LN10

---

**SYNTAX:** `Math.LN10`  
**DESCRIPTION:** The number value for the natural logarithm of 10. This value is represented internally as approximately 2.302585092994046.  
**EXAMPLE:** `var n = Math.LN10;`

---

### Math.LN2

---

**SYNTAX:** `Math.LN2`  
**DESCRIPTION:** The number value for the natural logarithm of 2. This value is represented internally as approximately 0.6931471805599453.  
**EXAMPLE:** `var n = Math.LN2;`

---

### Math.LOG2E

---

**SYNTAX:** `Math.LOG2E`  
**DESCRIPTION:** The number value for the base 2 logarithm of e, the base of the natural logarithms. This value is represented internally as approximately 1.4426950408889634. The value of `Math.LOG2E` is approximately the reciprocal of the value of `Math.LN2`.  
**EXAMPLE:** `var n = Math.LOG2E;`

---

### Math.LOG10E

---

**SYNTAX:** `Math.LOG10E`  
**DESCRIPTION:** The number value for the base 10 logarithm of e, the base of the natural logarithms. This value is represented internally as approximately 0.4342944819032518. The value of `Math.LOG10E` is approximately the reciprocal of the value of

---

---

### Math.LN10

EXAMPLE: `var n = Math.LOG10E`

---

### Math.PI

SYNTAX: `Math.PI`

DESCRIPTION: The number value for pi, the ratio of the circumference of a circle to its diameter. This value is represented internally as approximately 3.14159265358979323846.

EXAMPLE: `var n = Math.PI;`

---

### Math.SQRT1\_2

SYNTAX: `Math.SQRT1_2`

DESCRIPTION: The number value for the square root of 2, which is represented internally as approximately 0.7071067811865476. The value of `Math.SQRT1_2` is approximately the reciprocal of the value of [Math.SQRT2](#).

EXAMPLE: `var n = Math.SQRT1_2;`

---

### Math.SQRT2

SYNTAX: `Math.SQRT2`

DESCRIPTION: The number value for the square root of 2, which is represented internally as approximately 1.4142135623730951.

EXAMPLE: `var n = Math.SQRT2;`

---

## Math object static methods

### Math.abs()

SYNTAX: `Math.abs(x)`

WHERE: `x` - a number.

RETURN: number - the absolute value of `x`. Returns NaN if `x` cannot be converted to a number.

DESCRIPTION: Computes the absolute value of a number.

EXAMPLE: 

```
//The function returns the absolute value
// of the number -2 (i.e.
//the return value is 2):
var n = Math.abs(-2);
```

---

### Math.acos()

SYNTAX: `Math.acos(x)`

WHERE: `x` - a number between 1 and -1.

RETURN: number - the arc cosine of `x`.

DESCRIPTION: The return value is expressed in radians and ranges from 0 to pi. Returns NaN if `x` cannot be converted to a number, is greater than 1, or is less than -1.

EXAMPLE: `function compute_acos(x)`

---

---

```
    {
      return Math.acos(x)
    }

    // If you pass -1 to the function compute_acos(),
    // the return is the
    // value of pi (approximately 3.1415...),
    // if you pass 3 the
    // return is NaN since 3 is out
    // of the range of Math.acos.
```

---

## **Math.asin()**

---

**SYNTAX:** `Math.asin(x)`

**WHERE:** `x` - a number between 1.0 and -1.0

**RETURN:** number - implementation-dependent approximation of the arc sine of the argument.

**DESCRIPTION:** The return value is expressed in radians and ranges from  $-\pi/2$  to  $+\pi/2$ . Returns NaN if `x` cannot be converted to a number, is greater than 1, or less than -1.

**EXAMPLE:**

```
function compute_asin(x)
{
  return Math.asin(x)
}
//If you pass -1 to the function compute_acos(),
//the return is the
//value of -pi/2 , if you pass 3 the return is
//NaN since 3 is out of Math.acos's range.
```

---

## **Math.atan()**

---

**SYNTAX:** `Math.atan(x)`

**WHERE:** `x` - any number.

**RETURN:** number - an implementation-dependent approximation of the arctangent of the argument.

**DESCRIPTION:** The return value is expressed in radians and ranges from  $-\pi/2$  to  $+\pi/2$ .

**EXAMPLE:**

```
//The arctangent of x is returned
//in the following function:
function compute_arctangent(x)
{
  return Math.arctangent(x)
}
```

---

## **Math.atan2()**

---

**SYNTAX:** `Math.atan2(x, y)`

**WHERE:** `x` - x coordinate of the point.  
`y` - y coordinate of the point.

**RETURN:** number - an implementation-dependent approximation to the arc tangent of the quotient,  $y/x$ , of the arguments `y` and `x`, where the signs of the arguments are used to determine the quadrant of the

---

---

result.

DESCRIPTION: It is intentional and traditional for the two-argument arc tangent function that the argument named *y* be first and the argument named *x* be second. The return value is expressed in radians and ranges from  $-\pi$  to  $+\pi$ .

EXAMPLE: 

```
//The arctangent of the quotient y/x
//is returned in the
//following function:
function compute_arctangent_of_quotient(x, y)
{
    return Math.arctangent2(x, y)
}
```

---

### **Math.ceil()**

---

SYNTAX: `Math.ceil(x)`

WHERE: *x* - any number or numeric expression.

RETURN: number - the smallest number that is not less than the argument and is equal to a mathematical integer.

DESCRIPTION: If the argument is already an integer, the result is the argument itself. Returns NaN if *x* cannot be converted to a number.

EXAMPLE: 

```
//The smallest number that is
//not less than the argument and is
//equal to a mathematical integer is returned
//in the following function:
function compute_small_arg_eq_to_int(x)
{
    return Math.ceil(x)
}
```

---

### **Math.cos()**

---

SYNTAX: `Math.cos()`

WHERE: *x* - an angle, measured in radians.

RETURN: number - an implementation-dependent approximation of the cosine of the argument

DESCRIPTION: The argument is expressed in radians. Returns NaN if *x* cannot be converted to a number. In order to convert degrees to radians you must multiply by  $2\pi/360$ .

EXAMPLE: 

```
//The cosine of x is returned
//in the following function:
function compute_cos(x)
{
    return Math.cos(x)
}
```

---

### **Math.exp()**

---

SYNTAX: `Math.exp(x)`

WHERE: *x* - either a number or a numeric expression to be used as an exponent

RETURN: number - an implementation-dependent approximation of the

---

---

exponential function of the argument.

DESCRIPTION: For example returns e raised to the power of the x, where e is the base of the natural logarithms. Returns NaN if x cannot be converted to a number.

EXAMPLE: 

```
//The exponent of x is returned
//in the following function:
function compute_exp(x)
{
    return Math.exp(x)
}
```

---

## **Math.floor()**

---

SYNTAX: `Math.floor(x)`

WHERE: x - a number.

RETURN: number - the greatest number value that is not greater than the argument and is equal to a mathematical integer.

DESCRIPTION: If the argument is already an integer, the return value is the argument itself.

EXAMPLE: 

```
//The floor of x is returned
//in the following function:
function compute_floor(x)
{
    return Math.floor(x)
}
//If 6.78 is passed to compute_floor,
//7 will be returned. If 89.1
//is passed, 90 will be returned.
```

---

## **Math.log()**

---

SYNTAX: `Math.log(x)`

WHERE: x - a number.greater than zero.

RETURN: number - an implementation-dependent approximation of the natural logarithm of x.

DESCRIPTION: If a negative number is passed to `Math.log()`, the return is NaN

EXAMPLE: 

```
//The natural log of x is returned
//in the following function:
function compute_log(x)
{
    return Math.log(x)
}
//If the argument is less than 0 or NaN,
//the result is NaN
//If the argument is +0 or -0,
//the result is -infinity
//If the argument is 1, the result is +0
//If the argument is +infinity,
//the result is +infinity
```

---

## **Math.max()**

---

SYNTAX: `Math.max(x, y)`

---

---

WHERE:            **x - a number.**  
                  **y - a number.**

RETURN:           **number - the larger of x and y.**

DESCRIPTION:      **Returns NaN if either argument cannot be converted to a number.**

EXAMPLE:          

```
//The larger of x and y is returned
//in the following function:
function compute_max(x, y)
{
    return Math.max(x, y)
}
//If x = a and y = 4 the return is NaN
//If x > y the return is x
//If y > x the return is y
```

---

### **Math.min()**

---

SYNTAX:           **Math.min(x, y)**

WHERE:            **x - a number.**  
                  **y - a number.**

RETURN:           **number - the smaller of x and y. Returns NaN if either argument cannot be converted to a number.**

DESCRIPTION:      **Returns NaN if either argument cannot be converted to a number.**

EXAMPLE:          

```
//The smaller of x and y is returned
//in the following function:
function compute_min(x, y)
{
    return Math.min(x, y)
}
//If x = a and y = 4 the return is NaN
//If x > y the return is y
//If y > x the return is x
```

---

### **Math.pow()**

---

SYNTAX:           **Math.pow(x, y)**

WHERE:            **x - The number which will be raised to the power of y**  
                  **y - The number which x will be raised to**

RETURN:           **number - the value of x to the power of y.**

DESCRIPTION:      **If the result of Math.pow() is an imaginary or complex number, NaN will be returned. Please note that if Math.pow() unexpectedly returns infinity, it may be because the floating-point value has experienced overflow.**

EXAMPLE:          

```
//x to the power of y is returned
//in the following function:
function compute_x_to_power_of_y(x, y)
{
    return Math.pow(x, y)
}
//If the result of Math.pow is
//an imaginary or complex number,
//the return is NaN
```

---

---

```
//If y is NaN, the result is NaN
//If y is +0 or -0, the result is 1,
//even if x is NaN
//If x = 2 and y = 3 the return value is 8
```

---

## **Math.random()**

---

**SYNTAX:** `Math.random()`

**RETURN:** number - a number which is positive and pseudo-random and which is greater than or equal to 0 but less than 1.

**DESCRIPTION:** Calling this method numerous times will result in an established pattern (the sequence of numbers will be the same each time). This method takes no arguments. Seeding is not yet possible.

**SEE:** [Clib.rand\(\)](#)

**EXAMPLE:**

```
//Return a random number:
function compute_rand_num()
{
    return Math.rand()
}
```

---

## **Math.round()**

---

**SYNTAX:** `Math.round(x)`

**WHERE:** x - a number.

**RETURN:** number - value that is closest to the argument and is equal to a mathematical integer. x is rounded up if its fractional part is equal to or greater than 0.5 and is rounded down if less than 0.5.

**DESCRIPTION:** The value of `Math.round(x)` is the same as the value of `Math.floor(x+0.5)`, except when x is \*0 or is less than 0 but greater than or equal to -0.5; for these cases `Math.round(x)` returns \*0, but `Math.floor(x+0.5)` returns +0.

**SEE:** [Math.floor\(\)](#)

**EXAMPLE:**

```
//Return a mathematical integer:
function compute_int(x)
{
    return Math.round(x)
}
//If the argument is NaN, the result is NaN
//If the argument is already an integer
//such as any of the
//following values: -0, +0, 4, 9, 8;
//then the result is the
//argument itself.
//If the argument is .2, then the result is 0.
//If the argument is 3.5, then the result is 4
//Note: Math.round(3.5) returns 4,
//but Math.round(-3.5) returns -3.
```

---

## **Math.sin()**

---

**SYNTAX:** `Math.sin(x)`

**WHERE:** x - an angle in radians.

---

---

**RETURN:** number - the sine of  $x$ , expressed in radians.

**DESCRIPTION:** Returns NaN if  $x$  cannot be converted to a number. In order to convert degrees to radians you must multiply by  $2\pi/360$ .

**EXAMPLE:**

```
//Return the sine of x:
function compute_sin(x)
{
    return Math.sin(x)
}
//If the argument is NaN, the result is NaN
//If the argument is +0, the result is +0
//If the argument is -0, the result is -0
//If the argument is +infinity or -infinity,
//the result is NaN
```

---

## **Math.sqrt()**

---

**SYNTAX:** `Math.sqrt(x)`

**WHERE:**  $x$  - a number or numeric expression greater than or equal to zero.

**RETURN:** number - the square root of  $x$ .

**DESCRIPTION:** Returns NaN if  $x$  is a negative number or cannot be converted to a number.

**SEE:** [Math.exp\(\)](#)

**EXAMPLE:**

```
//Return the square root of x:
function compute_square_root(x)
{
    return Math.sqrt(x)
}
//If the argument is NaN, the result is NaN
//If the argument is less than 0,
//the result is NaN
//If the argument is +0, the result is +0
//If the argument is -0, the result is -0
//If the argument is +infinity,
//the result is +infinity
```

---

## **Math.tan()**

---

**SYNTAX:** `Math.tan(x)`

**WHERE:**  $x$  - an angle measured in radians.

**RETURN:** number - the tangent of  $x$ , expressed in radians.

**DESCRIPTION:** Returns NaN if  $x$  cannot be converted to a number. In order to convert degrees to radians you must multiply by  $2\pi/360$ .

**EXAMPLE:**

```
//Return the tangent of x:
function compute_tan(x)
{
    return Math.tan(x)
}
//If the argument is NaN, the result is NaN
//If the argument is +0, the result is +0
//If the argument is -0, the result is -0
//If the argument is +infinity or -infinity,
//the result is NaN
```

---

---

# Number Object

platform: All OS, All version of SE

## Number object instance methods

---

### Number toExponential()

**SYNTAX:** `number.toExponential(fractionDigits)`  
**WHERE:** `fractionDigits` - the digits after the significand's decimal point.  
**RETURN:** string - A string representation of this number in exponential notation.  
**DESCRIPTION:** This method returns a string containing the number represented in exponential notation with one digit before the significand's decimal point and `fractionDigits` digits after the significand's decimal point.

---

### Number toFixed()

**SYNTAX:** `number.toFixed(fractionDigits)`  
**WHERE:** `fractionDigits` - the digits after the decimal point.  
**RETURN:** string - A string representation of this number in fixed-point notation.  
**DESCRIPTION:** This method returns a string containing the number represented in fixed-point notation with `fractionDigits` digits after the decimal point.

---

### Number toLocaleString()

**SYNTAX:** `number.toLocaleString()`  
**RETURN:** string - a string representation of this number.  
**DESCRIPTION:** This method behaves like [Number toString\(\)](#) and converts a number to a string in a manner specific to the current locale. Such things as placement of decimals and comma separators are affected.  
**SEE:** [Number toString\(\)](#)  
**EXAMPLE:**  

```
var n = 8.9;  
var s = n.toLocaleString();
```

---

### Number toPrecision()

**SYNTAX:** `number.toPrecision(precision)`  
**WHERE:** `precision` - significant digits in fixed notation, or digits after the significand's decimal point in exponential notation.  
**RETURN:** string - A string representation of this number in either exponential notation or in fixed notation.  
**DESCRIPTION:** This method returns a string containing the number represented in either in exponential notation with one digit before the

---

---

significant's decimal point and precision-1 digits after the significant's decimal point or in fixed notation with precision significant digits.

---

## **Number toString()**

---

SYNTAX: `number.toString([radix])`

WHERE: `radix` - an optional radix, base number, determining the string representation of this number.

RETURN: string - a string representation of this number.

DESCRIPTION: This method behaves similarly to [Number toLocaleString\(\)](#) and converts a number to a string using a standard format for numbers. If the `radix` is specified, the string will have digits representing that number base.

SEE: [Number toLocaleString\(\)](#)

EXAMPLE: 

```
var n = 8.9;
var s = n.toString(); // "8.9"
```

```
var a = 16;
Screen.writeln(a.toString()); // "16"
Screen.writeln(a.toString(10)); // "16"
Screen.writeln(a.toString(16)); // "10"
Screen.writeln(a.toString(15)); // "11"
Screen.writeln(a.toString(8)); // "20"
Screen.writeln(a.toString(2)); // "10000"
```

---

---

# Object Object

platform: All OS, All version of SE

## Object object instance methods

### Object()

---

**SYNTAX:** `new Object([value])`  
**WHERE:** `value` - a value or variable, usually a primitive, to convert to an object.

**RETURN:** object - a new top level object.

**DESCRIPTION:** Create a new top level object. If a `value` is passed, convert the `value` to an object, else create a new object. The examples below illustrate several ways to use `Object()` and how to accomplish similar things using different strategies.

If `Object()` is invoked as a function instead of as a constructor (that is, without `new`), it performs a type conversion on `value`. That is, it returns `value` as data type `Object`.

**SEE:** [Internal objects](#)

**EXAMPLE:**

```

/*****
First we create var s as a string data type.
Then we will convert s to an object data type,
namely, to a String object.
*****/
// Create s as data type string
var s = 'my string';
// Display the data type 'string'
Screen.writeln(typeof s);
// Display 'my string'
Screen.writeln(s);

// Convert s to data type object (String object)
var o = new Object(s);
// Display the data type 'object'
Screen.writeln(typeof o);
// Display 'my string'
Screen.writeln(o);

/*****
Next we create var so as a String object --
in one statement.
*****/
// Create so as a String object in one statement
var so = new String('my string');
// Display the data type 'object'
Screen.writeln(typeof so);
// Display 'my string'
Screen.writeln(so);

/*****
Next we create var o as an Object object data type.
We add the property o.mystring.
Note that the property may be accessed as:
o.mystring
*****/
```

---

---

```
        or
        o['mystring']
        *****/
// Create a new top level object
var o = new Object();
// Add the property mystring
o.mystring = 'my string';
// Display the data type 'object'
Screen.writeln(typeof o);
// Display 'my string'
Screen.writeln(o.mystring);
// Display 'my string'
Screen.writeln(o['mystring']);
```

---

## **Object hasOwnProperty()**

---

**SYNTAX:** `object.hasOwnProperty(propertyName)`

**WHERE:** `property` - a string with the name of the property about which to query.

**RETURN:** `boolean` - indicating whether or not the current object has a property of the specified name.

**DESCRIPTION:** This method determines if the object has a property with the name `propertyName`. To return `true`, the property must be an instance property created for this instance of an object and may not be an inheritable or prototype property. This is almost the same as testing `defined(object[propertyName])`, except that undefined values are different from non-existent values, and the internal `_hasProperty()` method of the object may be called.

**EXAMPLE:**

```
function Atest()
{
    this.name = "";
} // Test

Atest.prototype.city = "Fort Worth";

var t = new Atest();

Screen.writeln(t.city); // Fort
Worth

Screen.writeln(t.hasOwnProperty("name")); // true
Screen.writeln(t.hasOwnProperty("city")); // false
```

---

## **Object isPrototypeOf()**

---

**SYNTAX:** `object.isPrototypeOf(variable)`

**WHERE:** `variable` - the object to test.

**RETURN:** `boolean` - `true` if `variable` is an object and the current object is present in the prototype chain of the object, otherwise it returns `false`.

**DESCRIPTION:** If `variable` is not an object, then this method immediately returns `false`. Otherwise, the method recursively searches the internal `prototype` property of the object and if at any point the

---

---

current object is equal to one of these prototype properties, then the method returns `true`.

---

### **Object propertyIsEnumerable()**

---

**SYNTAX:** `object.propertyIsEnumerable(propertyName)`  
**WHERE:** `property` - name of the property about which to query.

**RETURN:** `boolean` - `true` if the current object has an enumerable property of the specified name, otherwise `false`.

**DESCRIPTION:** If the current object has no property of the specified name, then `false` is immediately returned. If the property has the `DontEnum` attribute set, then `false` is returned. Otherwise, `true` is returned.

**EXAMPLE:**

```
function Atest()
{
    this.name = "";
} // Test

Atest.prototype.city = "Fort Worth";

var t = new Atest();

// Fort Worth
Screen.writeln(t.city);

// true
Screen.writeln(t.propertyIsEnumerable("name"));
// true
Screen.writeln(t.propertyIsEnumerable("city"));
```

---

### **Object toLocaleString()**

---

**SYNTAX:** `object.toLocaleString()`  
**RETURN:** `string` - a string representation of this object.

**DESCRIPTION:** This method is intended to provide a default `toLocaleString()` method for all objects. It behaves exactly as if `toString()` had been called on the original object.

**SEE:** [Object toString\(\)](#)

---

### **Object toSource()**

---

**SYNTAX:** `object.toSource()`  
**RETURN:** `string` - a string representation of this object, which can be evaluated or interpreted.

**DESCRIPTION:** An object may be represented by a string comprised of JavaScript statements which, when evaluated or interpreted, reproduce the object. The source string may be evaluated by `global.eval()` or by `SElib.interpret()`. It is sometimes convenient or powerful to use source strings, for example, in the Data object the **DSP object**.

Though the source string may be read by humans, it is daunting.

---

---

Remember, `toSource()` is designed for interpretation by the ScriptEase interpreters, not by users.

The example below compares source strings created by the Object `toSource()` method and the `global.ToSource()` function. In these examples, the source strings are identical, which is not guaranteed always to be so. But, no matter which one is used, the source strings can be evaluated or interpreted.

SEE: [Global.ToSource\(\)](#), [global.eval\(\)](#), [SElib.interpret\(\)](#)

```
EXAMPLE: // An Array
var a = [1, '2', 3];

Screen.writeln(a.toSource());
Screen.writeln();
Screen.writeln(ToSource(a));
Screen.writeln();
/*****
Displays:

((new Function("var tmp1 = [1,\"2\",3]; tmp1[\"0\"] = 1;
tmp1[\"1\"] = \"2\"; tmp1[\"2\"] = 3; return
tmp1;"))())

((new Function("var tmp1 = [1,\"2\",3]; tmp1[\"0\"] = 1;
tmp1[\"1\"] = \"2\"; tmp1[\"2\"] = 3; return
tmp1;"))())
*****/

// An Object
var o = {one:1, two:'2', three:3};

Screen.writeln(o.toSource());
Screen.writeln();
Screen.writeln(ToSource(o));
Screen.writeln();
/*****
Displays:

((new Function("var tmp1 = new Object();
tmp1[\"three\"] = 3;
tmp1[\"one\"] = 1; tmp1[\"two\"] = \"2\"; return
tmp1;"))())

((new Function("var tmp1 = new Object();
tmp1[\"three\"] = 3;
tmp1[\"one\"] = 1; tmp1[\"two\"] = \"2\"; return
tmp1;"))())
*****/
```

---

## Object toString()

SYNTAX: `object.toString()`

RETURN: string - a string representation of this object.

DESCRIPTION: When this method is called, the internal class property, `_class`, is retrieved from the current object. A string is then constructed whose contents are "[object classname]", where classname is the

---

---

value of the property from the current object. Note that this function is rarely called directly, rather it is called implicitly through such functions as [global.ToString\(\)](#).

SEE: [Object toLocaleString\(\)](#)

---

### **Object valueOf()**

---

SYNTAX: `object.valueOf()`

RETURN: object - the value of this object

DESCRIPTION: Generally, this method returns the object itself. However, if object is a wrapper for a host object, the host object may be returned. Such wrappers for host objects may be created with the Object constructor.

SEE: [Object toSource\(\)](#), [Object\(\)](#)

---

---

# RegExp Object

Regular expressions do not seem very regular to average people. Regular expressions are used to search text and strings, searches that are very powerful if a person makes the effort to learn how to use them. Simple searches may be done like the following:

```
var str = "one two three";
str.indexOf("two");    // == 4
```

The `String indexOf()` method searches `str` for "two" and returns the beginning position of "two", which is 4. What if you wanted to find "t" and "o" with or without any characters in between, an "o" only at the beginning of a string, or an "e" only at the end of a string? Before answering, lets consider wildcards.

Most computer users are familiar with wildcards in searching, especially since they may be used in finding files. For example, the DOS command:

```
dir t*o.bat
```

will list all files that begin with "t" and end "o" in the filename and that have an extension of "bat". JavaScript does not use wildcards to extend search capability. Instead, ECMAScript, the standard for JavaScript, has implemented regular expression searches that do everything that wildcards do and much, much more. Regular expressions follow the PERL standard, though the syntax has been made easier to read. Anyone who can use regular expressions in PERL already knows how to use JavaScript regular expressions. For advanced information on regular expressions, there are many books in the PERL community, in addition to JavaScript books, that explain regular expressions.

Now lets answer the question about how to find the three cases mentioned above.

```
var str = "one two three";
var pat = /t.*o/;
str.search(pat);    // == 4
```

This fragment illustrates one way to use regular expressions to find "t" followed by "o" with any number of characters between them. Two things are different. One the variable `pat` which is assigned `/t.*o/`. The slashes indicate the beginning and end of a regular expression pattern, similar to how quotation marks indicate a string. The `String search()` method is a method of the `String` object that uses a regular expression pattern to search a string, similar to the `String indexOf()` method. In fact, they both return 4, the start position of "two", in these examples.

The `String object` has three methods for searching using regular expression patterns. The three methods are:

```
String match()
String replace()
String search()
```

The methods in the `RegExp` object, for using regular expressions, are explained below in this section. Before we move on to the cases of an "o" at the start or an "e" at the end of a string, consider the current example a little further. What do the slashes `/ . . . /` do? First, they define a regular expression pattern. Second,

they create a `RegExp` object. In our example, the quotes cause `str` to be a `String` object, and the slashes cause `pat` to be a `RegExp` object. Thus, `pat` may be used with `RegExp` methods and with the three `String` methods that use regular expression patterns.

```
var str = "one two three";
var pat = /t.*o/;
pat.test(str);    // == true
```

By using a method, such as `test()`, of the `RegExp` object, the string to be searched becomes the argument rather than the pattern to search for, as with the `String` methods. The `RegExp test()` method simply returns `true` or `false` indicating whether the pattern is found in the string.

```
var str = "one two three";
var pat = /t.*o/;
str.match(pat);    // == an Array with pertinent info
pat.exec(str);    // == an Array with pertinent info
```

The `String match()` and `RegExp exec()` methods return very similar, often the same, results in an `Array`. The return may vary depending on exactly which attributes, discussed later, are set for a regular expression.

To find an "o" only at the start of a string, use something like:

```
var str = "one two three";
var pat = /^o/;
str.search(pat);    // == 0
```

The caret "^" has a special meaning, namely, the start of a string or line. It anchors the characters that follow to the start of a string or line and is one of the special anchor characters.

To find an "e" only at the end of a string, use something like:

```
var str = "one two three";
var pat = /e$/;
str.search(pat);    // == 12
```

The dollar sign "\$" has a special meaning, namely, the end of a string or line. It anchors the characters that follow to the end of a string or line and is one of the special anchor characters.

Note that there is a very important distinction between searching for pattern matches using the `String` methods and using the `RegExp` methods. The `RegExp` methods execute much faster, but the `String` methods are often quicker to program. So, if you need to do intensive searching in which a single regular expression pattern is used many times in a loop, use the `RegExp` methods. If you just need to do a few searches, use the `String` methods. Every time a `RegExp` object is constructed using `new`, the pattern is compiled into a form that can be executed very quickly. Every time a new pattern is compiled using the `RegExp compile()` method, a pattern executes much faster. Other than the difference in speed and script writing time, the choice of which methods to use depends on personal preferences and the particular tasks at hand.

In general, the `RegExp` object allows the use of regular expression patterns in searches of strings or text. The syntax follows the ECMAScript standard, which may be thought of as a large and powerful subset of PERL regular expressions.

## Regular expression syntax

The general form for defining a regular expression pattern is:

```
/characters/attributes
```

Assume that we are searching the string "THEY, the three men, left". The following are valid regular expression patterns followed by a description of what they find:

```
/the three/      // "the three"  
/THE THREE/ig   // "the three"  
/th/            // "th" in "the"  
/th/igm         // "th" in "THEY", "the", and "three"
```

The slashes delimit the characters that define a regular expression. Everything between the **slashes** is part of a **regular expression**, just as everything between quotation marks is part of a string. Three letters may occur after the second slash that are not part of the regular expression. Instead, they define **attributes** of the regular expression. Any one, two, or three of the letters may be used, that is, any one or more of the attributes may be defined. Thus, a regular expression has three elements: literals, characters, and attributes.

### Regular expression literals

Regular expression literals delimit a regular expression pattern. The literals are a slash "/" at the beginning of some characters and a slash "/" at the end of the characters. These regular expression literals operate in the same way as quotation marks do for string literals. The following two lines of code accomplish the same thing, namely, they define and create an instance of a **RegExp object**:

```
var re = /^THEY/;  
var re = new RegExp("^THEY");
```

and so do the following two lines:

```
var re = /^THEY/i;  
var re = new RegExp("^THEY", "i");
```

### Regular expression characters

Each character or special character in a regular expression represents one character. Though some special characters, such as, the range of lowercase characters represented by `[a-z]`, may have multiple matches, only one at a time is matched. Thus, `[a-z]` will only find one of these 26 characters at one position in a string being searched. Just as strings have special characters, namely, escape sequences, regular expression patterns have various kinds of special characters and metacharacters that are explained below.

### Regular expression attributes

The following table lists allowable attribute characters and their effects on a regular expression. No other characters are allowed as attributes.

Character	Attribute meaning
-----------	-------------------

g	Do a global match. Allow the finding of all matches in a string using the <code>RegExp</code> and <code>String</code> methods and properties that allow global operations. The instance property <code>global</code> is set to <code>true</code> .
---	--

Example: `/pattern/g`

i Do case insensitive matches. The instance property `ignoreCase` is set to `true`.

Example: `/pattern/i`

m Work with multiple lines in a string. When working with multiple lines the `^` and `$` anchor characters will match the start and end of a string and the start and end of lines within the string. The newline character `\n` in a string indicates the end of a line and hence lines in a string. The instance property `multiline` is set to `true`.

Example: `/pattern/m`

Attributes are the characters allowed after the end slash `/` in a regular expression pattern. The following regular expressions illustrate the use of attributes.

```
var pat = /^The/i;    // any form of "the" at start of a string
var pat = /the/g;    // all occurrences of "the" may be found
var pat = /test$/m;  // first "test" at the end of any line
var pat = /test$/igm; // all forms of "test" at end of all lines
// The following four examples do the same as the first four
var pat = new RegExp("^The", "i");
var pat = new RegExp("the", "g");
var pat = new RegExp("test$", "m");
var pat = new RegExp("test$", "igm");
```

## Regular expression special characters

Regular expressions have many special characters, which are also known as metacharacters, with special meanings in a regular expression pattern. Some are simple escape sequences, such as, a newline `\n`, with the same meaning as the same escape sequence in strings. But, regular expressions have many more special characters that add much power to working with strings and text, much more power than is initially recognized by people being introduced to regular expressions. For anyone who works with strings and text, the effort to become proficient with regular expression parsing is more than worthwhile.

### Regular expression summary

Search pattern

<code>?</code>	zero or one of previous, <code>{0,1}</code>	<code>be?t</code>
<code>*</code>	zero or more of previous, maximal, <code>{0,}</code>	<code>b.*t</code>
<code>*?</code>	zero or more of previous, minimal, <code>{0,}?</code>	<code>b.*?t</code>
<code>+</code>	one or more of previous, maximal, <code>{1,}</code>	<code>b.+t</code>
<code>+</code>	one or more of previous, minimal, <code>{1,}?</code>	<code>b.+?t</code>
<code>{n}</code>	n times of previous	<code>be{n}t</code>
<code>{n,}</code>	n or more times of previous, maximal	<code>b.{n,}t</code>
<code>{n,}?</code>	n or more times of previous, minimal	<code>b.{n,}?t</code>
<code>{n,m}</code>	n to m times of previous	<code>be{1,2}t</code>
<code>.</code>	any character	<code>b.t</code>
<code>[]</code>	any one character in a class	<code>[a-m]</code>
<code>[^]</code>	any one not in a character class	<code>[^a-m]</code>
<code>[\b]</code>	one backspace character	<code>my[\b]word</code>

<code>\d</code>	any one digit, [0-9]	<code>file\d</code>
<code>\D</code>	any one not digit, [^0-9]	<code>file\D</code>
<code>\s</code>	any one white space character, [ \t\n\r\f\v]	<code>my\sword</code>
<code>\S</code>	any one not white space character, [^\t\n\r\f\v]	<code>my \sord</code>
<code>\w</code>	any one word character, [a-zA-Z0-9_]	<code>my big\w</code>
<code>\W</code>	any one not word character, [^a-zA-Z0-9_]	<code>my\Wbig</code>
<code>^</code>	anchor to start of string	<code>^string</code>
<code>\$</code>	anchor to end of string	<code>string\$</code>
<code>\b</code>	anchor to word boundary	<code>\bbig</code>
<code>\B</code>	anchor to not word boundary	<code>\Bbig</code>
<code> </code>	or	<code>(bat) (bet)</code>
<code>\n</code>	group n	<code>(bat)a\1</code>
<code>()</code>	group	<code>my(?:)fil</code>
<code>(?:)</code>	group without capture	<code>my(?:)fil</code>
<code>(?=)</code>	group without capture with positive look ahead	<code>my(?!?)fil</code>
<code>(?!)</code>	group without capture with negative look ahead	<code>my(?!?)fil</code>
<code>\f</code>	form feed character	<code>string\f</code>
<code>\n</code>	newline	<code>string\n</code>
<code>\r</code>	carriage return character	<code>string\r</code>
<code>\t</code>	horizontal tab character	<code>one\tfour</code>
<code>\v</code>	vertical tab character	<code>one\vtwo</code>
<code>/</code>	/ character	<code>\/fil</code>
<code>\\</code>	\ character	<code>\\fil</code>
<code>\.</code>	. character	<code>fil\.bak</code>
<code>\*</code>	* character	<code>one\*two</code>
<code>\+</code>	+ character	<code>\+fil</code>
<code>\?</code>	? character	<code>when\?</code>
<code> </code>	character	<code>one\ two</code>
<code>\(</code>	( character	<code>\(fil\)</code>
<code>\)</code>	) character	<code>\(fil\)</code>
<code>\[</code>	[ character	<code>\[fil\]</code>
<code>\]</code>	] character	<code>\[fil\]</code>
<code>\{</code>	{ character	<code>\{fil\}</code>
<code>\}</code>	} character	<code>\{fil\}</code>
<code>\C</code>	a character itself. Seldom used.	<code>b\at</code>
<code>\cC</code>	a control character	<code>one\cIfour</code>
<code>\x##</code>	character by hexadecimal code	<code>\x41</code>
<code>\###</code>	character by octal code	<code>\101</code>

#### Replace pattern

<code>\$n</code>	group n in search pattern, \$1, \$2, . . . \$9	<code>big\$1</code>
<code>\$+</code>	last group in search pattern	<code>big\$+</code>
<code>\$`</code>	text before matched pattern	<code>big\$`</code>
<code>\$'</code>	text after matched pattern	<code>big\$'</code>
<code>\$&amp;</code>	text of matched pattern	<code>big\$&amp;</code>
<code>\\$</code>	\$ character	<code>big\\$</code>

### Regular expression repetition characters

Notice that the character "?" pulls double duty. When used as the only repetition specifier, "?" means to match zero or more occurrences of the previous character. For example, /a?/ matches one or more "a" characters in sequence. When used as the second character of a repetition specifier, as in "\*?", "+?", and "{n, }?", a question mark "?" indicates a minimal match. What is meant by a minimal match?

Well obviously, it is the counterpart to a maximal match, which is the default for JavaScript and PERL regular expressions. A maximal match will include the maximum number of characters in a text that will qualify to match a regular expression pattern. For example, in the string "one two three", the pattern /o.\*e/ will match the text "one two three". Why? The pattern says to match text that begins with the character "o" followed by zero or more of any characters up to the character "e". Since the default is a maximal match, the whole string is matched since it begins with "o" and ends with "e". Often, this maximal match behavior is not what is expected or desired.

Now consider a similar match using the minimal character. The string is still "one two three", but the pattern becomes /o.\*?e/. Notice that the only difference is the addition of a question mark "?" as the second repetition character after the "\*". The text matched this time is "one", which is the minimal number of characters that match the conditions of the regular expression pattern.

So, it might be a good habit to begin reading regular expression patterns with a maximal and minimal vocabulary. As an example, let's spell out how we could read the two patterns in the current example.

- "o.\*e" - match text that begin with "o" and has the maximum number of characters possible until the last "e" is encountered.
- "o.\*?e" - match text that begins with "o" and has the minimum number of characters possible until the first "e" is encountered.

Sometimes a maximal match is called a greedy match and a minimal match is called a non-greedy match.

### **Repetition    How many characters matched**

?	Match zero or one occurrence of the previous character or sub pattern. Same as {0, 1}
*	Match zero or more occurrences of the previous character or sub pattern. A maximal match, that is, match as many characters as will fulfill the regular expression. Same as {0, }
*?	Match zero or more occurrences of the previous character or sub pattern. A minimal match, that is, match as few characters as will fulfill the regular expression. Same as {0, }?
+	Match one or more occurrences of the previous character or sub pattern. A maximal match, that is, match as many characters as will fulfill the regular expression. Same as {1, }
+?	Match one or more occurrences of the previous character or sub pattern. A minimal match, that is, match as few characters as will

	fulfill the regular expression. Same as <code>{1,}</code> ?
<code>{n}</code>	Match <i>n</i> occurrences of the previous character or sub pattern.
<code>{n,}</code>	Match <i>n</i> or more occurrences of the previous character or sub pattern. A maximal match, that is, match as many characters as will fulfill the regular expression.
<code>{n,}?</code>	Match <i>n</i> or more occurrences of the previous character or sub pattern. A minimal match, that is, match as few characters as will fulfill the regular expression.
<code>{n, m}</code>	Match the previous character or sub pattern at least <i>n</i> times but not more than <i>m</i> times.

## Regular expression character classes

Class	Character matched
<code>.</code>	Any character except newline, <code>[^\n]</code>
<code>[...]</code>	Any one of the characters between the brackets
<code>[^...]</code>	Any one character not one of the characters between the brackets
<code>[\b]</code>	A backspace character (special syntax because of the <code>\b</code> boundary)
<code>\d</code>	Any digit, <code>[0-9]</code>
<code>\D</code>	Any character not a digit, <code>[^0-9]</code>
<code>\s</code>	Any white space character, <code>[\t\n\r\f\v]</code>
<code>\S</code>	Any non-white space character, <code>[^\t\n\r\f\v]</code>
<code>\w</code>	Any word character, <code>[a-zA-Z0-9_]</code>
<code>\W</code>	Any non-word character, <code>[^a-zA-Z0-9_]</code>

## Regular expression anchor characters

Anchor characters indicate that the following or preceding characters must be next to a special position in a string. The characters next to anchor characters are included in a match, not the anchor characters themselves. For example, in the string "The big cat and the small cat", the regular expression `/cat$/` will match the "cat" at the end of the string, and the match will include only the three characters "cat". The "\$" is an anchor character indicating the end of a string (or line if a multiline search is being done).

The following table lists the anchor characters, metacharacters, and their meanings.

Character	Anchor meaning
<code>^</code>	The beginning of a string (or line if doing a multiline search). (See <code>\A</code> below.) Example: <code>/^The/</code>
<code>\$</code>	The end of a string (or line if doing a multiline search). (See <code>\Z</code> below.)

Example: `/cat$/`

- `\A` Matches the beginning of a string only. (See `$` above.)
- `\b` A word boundary. Match any character that is not considered to be a valid character for a word in programming. The character class `"\W"`, not a word character, is similar. There are two differences. One, `"\b"` also matches a backspace. Two, `"\W"` is included in a match, since it is regular expression character, but `"\b"` is not included in a match.  
Example: `/\bthe\b/`
- `\B` Not a word boundary. The character class `"\w"` is similar. The most notable difference is that `"\w"` is included in a match, and `"\B"` is not.  
Example: `/l\B/`
- `\Z` Matches the end of a string only. (See `^` above.)

## Regular expression reference characters

Character	Meaning
-----------	---------

- |                      |   |
|----------------------|---|
| <code> </code>       | Or. Match the character or sub pattern on the left <b>or</b> the character or sub pattern on the right.   |
| <code>\n</code>      | Reference to group. Match the same characters, not the regular expression itself, matched by group <code>n</code> . Groups are sub patterns that are contained in parentheses. Groups may be nested. Groups are numbered according to the order in which the left parenthesis of a group appears in a regular expression.   |
| <code>(...)</code>   | Group with capture. Characters inside of parentheses are handled as a single unit or sub pattern in specified ways, such as with the first two explanations, <code> </code> and <code>\n</code> , in this table. The characters that are actually matched are captured and may be used later in an expression (as with <code>\n</code> ) or in a replacement expression (as with <code>\$n</code> ). For example, if the string "one two three two one" and the pattern <code>/(o.e) .+(w.+?e)/</code> are used, then the back references <code>\$1</code> or <code>\1</code> use the text "one".   |
| <code>(?:...)</code> | Group without capture. Matches the same text as <code>(...)</code> , but the text matched is not captured or saved and is not available for later use using <code>\n</code> or <code>\$n</code> . The overhead of not capturing matched text becomes important in faster execution time for searches involving loops and many iterations. Also, some expressions and replacements can be easier to read and use with fewer numbered back references with which to keep up. For example, if the string "one two three two one" and the pattern <code>/(?:o.e) .+(w.+?e)/</code> are used, then the back references <code>\$1</code> or <code>\1</code> use the text "wo thre". |
| <code>(?=...)</code> | Positive look ahead group without capture. The position of the match is at the beginning of the text that matches the sub pattern. For example, <code>/ScriptEase (?:=Desktop ISDK)/</code> matches "ScriptEase " in "ScriptEase Desktop" or "ScriptEase ISDK", but   |

not "ScriptEase " in "ScriptEase Web Server". When a search continues, it begins after "ScriptEase ", not after "Desktop" or "ISDK". That is, the search continues after the last text matched, not after the text that matches the look ahead sub pattern.

(?!... ) Negative look ahead group without capture. The position of the match is at the beginning of the text not matching the sub pattern. For example, /ScriptEase (?!Desktop|ISDK)/ matches "ScriptEase " in "ScriptEase Web Server", but not "ScriptEase " in "ScriptEase Desktop" or "ScriptEase ISDK". When a search continues, it begins after "ScriptEase ", not after "Desktop" or "ISDK". That is, the search continues after the last text matched, not after the text that matches the look ahead sub pattern.

## Regular expression escape sequences

### Sequence Character represented

\f	Form feed, \cL, \x0C, \014
\n	Line feed, newline, \cJ, \x0A, \012
\r	Carriage return, \cM, \x0D, \015
\t	Horizontal tab, \cI, \x09, \011
\v	Vertical tab, \cK, \x0B, \013
\/	The character: /
\\	The character: \
\.	The character: .
\*	The character: *
\+	The character: +
\?	The character: ?
\	The character:
\(	The character: (
\)	The character: )
\[	The character: [
\]	The character: ]
\{	The character: {
\}	The character: }
\c	A character itself, if not one of the above. Seldom, if ever, used.
\cC	A control character. For example, \cL is a form feed (^L or Ctrl-L), same as \f.
\x##	A character represented by its code in hexadecimal. For example, \x0A is a newline, same as \n, and \x41 is "A".
\###	A character represented by its code in octal. For example, \012 is a

newline, same as `\n`, and `\101` is "A".

## Regular expression replacement characters

All of the special characters that have been discussed so far pertain to regular expression patterns, that is, to finding and matching strings and patterns in a target string. If all you want to do is find text, then you do not need to know about regular expression replacement characters. However, most people not only want to do powerful searches, but they also want to make powerful replacements of found text. This section describes special characters that are used in replacement strings and that are related to special characters used in search patterns.

Expression	Meaning
<code>\$1</code> , <code>\$2</code> ... <code>\$9</code>	The text that is matched by sub patterns inside of parentheses. For example, <code>\$1</code> substitutes the text matched in the first parenthesized group in a regular expression pattern. See the groups, <code>(...)</code> , <code>(?:...)</code> , <code>(?=...)</code> , and <code>(?!...)</code> , under <a href="#">regular expression reference characters</a> .
<code>\$+</code>	The text matched by the last group, that is, parenthesized sub pattern.
<code>\$`</code>	The text before, to the left of, the text matched by a pattern.
<code>\$'</code>	The text after, to the right of, the text matched by a pattern
<code>\$&amp;</code>	The text matched by a pattern
<code>\\$</code>	A literal dollar sign, <code>\$</code> .

## Regular expression precedence

The patterns, characters, and metacharacters of regular expressions comprise a sub language for working with strings. Some of the metacharacters can be understood as operators, and, like operators in all programming languages, there is an order of precedence. The following tables list regular expression operators in the order of their precedence.

Operator	Descriptions
<code>\</code>	Escape
<code>()</code> , <code>(?:)</code> , <code>(?=)</code> , <code>(?!)</code> , <code>[]</code>	Groups and sets
<code>*</code> , <code>+</code> , <code>?</code> , <code>{n}</code> , <code>{n,}</code> , <code>{n,m}</code>	Repetition
<code>^</code> , <code>\$</code> , <code>\metacharacter</code>	Anchors and metacharacters
<code> </code>	Alternation

## RegExp object instance properties

### RegExp global

---

SYNTAX:	<code>regexp.global</code>
DESCRIPTION:	A read-only property of an instance of a <a href="#">RegExp object</a> . It is <code>true</code> if "g" is an attribute in the regular expression pattern being

---

---

used.

Read-only property. Use `RegExp compile()` to change.

SEE: [Regular expression attributes](#)

EXAMPLE: 

```
var pat = /^Begin/g;
//or
var pat = new RegExp("^Begin", "g");
```

---

## RegExp ignoreCase

---

SYNTAX: `regexp.ignoreCase`

DESCRIPTION: A read-only property of an instance of a **RegExp object**. It is `true` if "i" is an attribute in the regular expression pattern being used.

Read-only property. Use `RegExp compile()` to change.

SEE: [Regular expression attributes](#)

EXAMPLE: 

```
var pat = /^Begin/i;
//or
var pat = new RegExp("^Begin", "i");
```

---

## RegExp lastIndex

---

SYNTAX: `regexp.lastIndex`

DESCRIPTION: The character position after the last pattern match and which is the basis for subsequent matches when finding multiple matches in a string. That is, in the next search, `lastIndex` is the starting position. This property is used only in global mode after being set by using the "g" attribute when defining or compiling a search pattern. **RegExp exec()** and **RegExp test()** use and set the `lastIndex` property. If a match is not found by one of them, then `lastIndex` is set to 0. Since the property is read/write, you may set the property at any time to any position.

Read/write property.

SEE: [RegExp exec\(\)](#), [String match\(\)](#)

EXAMPLE: 

```
var str = "one tao three tio one";
var pat = /t.o/g;
pat.exec(str);
// pat.lastIndex == 7
```

---

## RegExp multiline

---

SYNTAX: `regexp.multiline`

DESCRIPTION: A read-only property of an instance of a **RegExp object**. It is `true` if "m" is an attribute in the regular expression pattern being used. There is no static (or global) `RegExp multiline` property in ScriptEase JavaScript since the presence of one is based on old technology and is confusing now that an instance property exists.

This property determines whether a pattern search is done in a multiline mode. When a pattern is defined, the `multiline`

---

---

attribute may be set, for example, `/^t/m`. A pattern definition such as this one, sets the instance property `regexp.multiline` to `true`.

Read-only property. Use [RegExp compile\(\)](#) to change.

SEE: [Regular expression attributes](#)

EXAMPLE: 

```
// In all these examples, pat.multiline is set
// to true. If there were no "m" in the attributes,
// then pat.multiline would be set to false.
var pat = /^Begin/m;
//or
var pat = new RegExp("^Begin", "igm");
//or
var pat = /^Begin/m;
//or
var pat = new RegExp("^Begin", "igm");
```

---

## RegExp source

---

SYNTAX: `regexp.source`

DESCRIPTION: The regular expression pattern being used to find matches in a string, not including the attributes.

Read-only property. Use [RegExp compile\(\)](#) to change.

SEE: [Regular expression syntax](#)

EXAMPLE: 

```
var str = "one tao three tio one";
var pat = /t.o/g;
pat.exec(str);
// pat.source == "t.o"
```

---

## RegExp returned array properties

Some methods, [String match\(\)](#) and [RegExp exec\(\)](#) return arrays in which various elements and properties are set that provide more information about the last regular expression search. The properties that might be set are described in this section, not the contents of the array elements.

### index (RegExp)

---

SYNTAX: `returnedArray.index`

DESCRIPTION: When [String match\(\)](#) is called and the "g" is not used in the regular expression, `String match()` returns an array with two extra properties, `index` and `input`. The property `index` has the start position of the match in the target string.

SEE: [input \(RegExp\)](#), [RegExp exec\(\)](#), [String match\(\)](#)

EXAMPLE: 

```
var str = "one tao three tio one";
var pat = /(t.o)\s(t.r)/g;
var rtn = pat.exec(str);
// rtn[0] == "tao thr"
// rtn[1] == "tao"
// rtn[2] == "thr"
// rtn.index == 4
// rtn.input == "one tao three tio one"
```

---

## input (RegExp)

---

**SYNTAX:** `returnedArray.input`

**DESCRIPTION:** When `String match()` is called and the "g" is not used in the regular expression, `String match()` returns an array with two extra properties, `index` and `input`. The property `input` has a copy of the target string.

**SEE:** [index \(RegExp\)](#), [RegExp exec\(\)](#), [String match\(\)](#)

**EXAMPLE:**

```
var str = "one two three two one";
var pat = /(t.o)\s(t.r)/g;
var rtn = pat.exec(str);
// rtn[0] == "two thr"
// rtn[1] == "two"
// rtn[2] == "thr"
// rtn.index == 4
// rtn.input == "one two three two one"
```

---

## RegExp object instance methods

### RegExp()

---

**SYNTAX:** `new RegExp([pattern[, attributes]])`

**WHERE:** `pattern` - a string containing a regular expression pattern to use with this **RegExp object**.

`attributes` - a string with the attributes for this **RegExp object**.

**RETURN:** `object` - a new regular expression object, or `null` on error.

**DESCRIPTION:** Creates a new regular expression object using the search pattern and options if they are specified.

If the attributes string is passed, it must contain one or more of the following characters or be an empty string "":

- `i` - sets the `ignoreCase` property to `true`
- `g` - sets the `global` property to `true`
- `m` - set the `multiline` property to `true`

**SEE:** [Regular expression syntax](#), [String match\(\)](#), [String replace\(\)](#), [String search\(\)](#)

**EXAMPLE:**

```
// no options
var regobj = new RegExp( "r*t", "" );
// ignore case
var regobj = new RegExp( "r*t", "i" );
// global search
var regobj = new RegExp( "r*t", "g" );
// set both to be true
var regobj = new RegExp( "r*t", "ig" );
```

---

### RegExp compile()

---

**SYNTAX:** `regex.compile(pattern[, attributes])`

**WHERE:** `pattern` - a string with a new regular expression pattern to use with this **RegExp object**.

`attributes` - a string with the new attributes for this **RegExp**

---

---

	object.
RETURN:	void.
DESCRIPTION:	<p>This method changes the pattern and attributes to use with the current instance of a <b>RegExp object</b>. An instance of a <b>RegExp</b> object may be used repeatedly by changing it with this method.</p> <p>If the attributes string is supplied, it must contain one or more of the following characters or be an empty string "":</p> <ul style="list-style-type: none"> <li>i - sets the ignoreCase property to true</li> <li>g - sets the global property to true</li> <li>m - set the multiline property to true</li> </ul>
SEE:	<a href="#">RegExp()</a> , <a href="#">Regular expression syntax</a>
EXAMPLE:	<pre>var regobj = new RegExp("now"); // use this RegExp object regobj.compile("r*t"); // use it some more regobj.compile("t.+o", "ig"); // use it some more</pre>

---

## RegExp exec()

---

SYNTAX:	<code>regexp.exec([str])</code>
WHERE:	<p><code>str</code> - a string on which to perform a regular expression match.</p> <p>Default is <code>RegExp.input</code>.</p>
RETURN:	<p>array - an array with various elements and properties set depending on the attributes of a regular expression. Returns <code>null</code> if no match is found.</p>
DESCRIPTION:	<p>This method, of all the <b>RegExp</b> and <b>String</b> methods, is both the most powerful and most complex. For many, probably most, searches, other methods are quicker and easier to use. A string, the target, to be searched is passed to <code>exec()</code> as a parameter. If no string is passed, then <b>RegExp.input</b>, which is a read/write property, is used as the target string.</p> <p>When executed without the global attribute, "g", being set, if a match is found, element 0 of the returned array is the text matched, element 1 is the text matched by the first sub pattern in parentheses, element 2 the text matched by the second sub pattern in parentheses, and so forth. These elements and their numbers correspond to groups in regular expression patterns and replacement expressions. The <code>length</code> property indicates how many text matches are in the returned array. In addition, the returned array has the <code>index</code> and <code>input</code> properties. The <code>index</code> property has the start position of the first text matched, and the <code>input</code> property has the target string that was searched. These two properties are the same as those that are part of the returned array from <b>String match()</b> when used without its global attribute being set.</p> <p>When executed with the global attribute being set, the same</p>

---

---

results as above are returned, but the behavior is more complex which allows further operations. This method `exec()` begins searching at the position, in the target string, specified by `this.lastIndex`. After a match, `this.lastIndex` is set to the position after the last character in the text matched. Thus, you can easily loop through a string and find all matches of a pattern in it. The property `this.lastIndex` is read/write and may be set at anytime. When no more matches are found, `this.lastIndex` is reset to 0.

Since `RegExp.exec()` always includes all information about a match in its returned array, it is the best, perhaps only, way to get all information about all matches in a string.

As with `String.match()`, if any matches are made, appropriate `RegExp` object static properties, such as `RegExp.leftContext`, `RegExp.rightContext`, `RegExp.$n`, and so forth are set, providing more information about the matches.

SEE: [String.match\(\)](#), [RegExp object static properties](#)

EXAMPLE:

```
var str = "one two three tio one";
var pat = new RegExp("t.o", "g");

while ((rtn = pat.exec(str)) != null)
    Screen.writeln("Text = " + rtn[0] +
                  " Pos = " + rtn.index +
                  " End = " + pat.lastIndex);

// Display is:
// Text = two Pos = 4 End = 7
// Text = tio Pos = 14 End = 17
```

---

## RegExp.test()

---

SYNTAX: `regexp.test([str])`  
WHERE: `str` - a string on which to perform a regular expression match.  
Default is `RegExp.input`.

RETURN: `boolean` - `true` if there is a match, else `false`.

DESCRIPTION: Tests a string to see if there is a match for a regular expression pattern.

This method is equivalent to `regexp.exec(string) != null`.

If there is a match, appropriate `RegExp` object static properties, such as `RegExp.leftContext`, `RegExp.rightContext`, `RegExp.$n`, and so forth, are set, providing more information about the matches.

Though it is unusual, `test()` may be used in a special way when the global attribute, "g", is set for a regular expression pattern. Like with `RegExp.exec()`, when a match is found, the `lastIndex` property is set to the character position after the text match. Thus, `test()` may be used repeatedly on a string, though there are few reasons to do so. One reason would be if you only wanted to know if a string had more than one match.

---

---

SEE: [RegExp exec\(\)](#), [String match\(\)](#), [String search\(\)](#)

EXAMPLE: 

```
var rtn;
var str = "one two three tio one";
var pat = /t.o/;
    // rtn == true
rtn = pat.test(str);
```

---

## RegExp object static properties

### RegExp.\$n

---

SYNTAX: `RegExp.$n`  
DESCRIPTION: The text matched by the  $n^{\text{th}}$  group, that is, the  $n^{\text{th}}$  sub pattern in parenthesis. The numbering corresponds to `\n`, back references in patterns, and `$n`, substitutions in replacement patterns.  
  
Read-only property.

SEE: [Regular expression reference characters](#), [regular expression replacement characters](#)

EXAMPLE: 

```
var str = "one two three two one";
var pat = /(t.o)\s/
str.match(pat)
    // RegExp.$1 == "two"
```

---

### RegExp.input

---

SYNTAX: `RegExp.input`  
DESCRIPTION: If no string is passed to [RegExp exec\(\)](#) or to [RegExp test\(\)](#), then `RegExp.input` is used as the target string. To be used as the target string, it must be assigned a value. `RegExp.input` is equivalent to `RegExp.$_`, for compatibility with PERL.  
  
Read/write property.

SEE: [RegExp exec\(\)](#), [RegExp test\(\)](#)

EXAMPLE: 

```
var pat = /(t.o/;
RegExp.input = "one two three two one";
pat.exec();
    // "two" is matched
```

---

### RegExp.lastMatch

---

SYNTAX: `RegExp.lastMatch`  
DESCRIPTION: This property has the text matched by the last pattern search. It is the same text as in element 0 of the array returned by some methods. `RegExp.lastMatch` is equivalent to `RegExp["$&"]`, for compatibility with PERL.  
  
Read-only property.

SEE: [RegExp exec\(\)](#), [String match\(\)](#), [RegExp returned array properties](#)

EXAMPLE: 

```
var str = "one two three two one";
var pat = /(t.o)/
pat.exec(str);
    // RegExp.lastMatch == "two"
```

---

## RegExp.lastParen

---

SYNTAX: `RegExp.lastParen`

DESCRIPTION: This property has the text matched by the last group, parenthesized sub pattern, in the last pattern search. `RegExp.lastParen` is equivalent to `RegExp["$+"]`, for compatibility with PERL.

Read-only property.

SEE: [RegExp.\\$n](#)

EXAMPLE: 

```
var str = "one two three two one";
var pat = /(t.o)+\s(t.r)/
pat.exec(str);
// RegExp.lastParen == "thr"
```

---

## RegExp.leftContext

---

SYNTAX: `RegExp.leftContext`

DESCRIPTION: This property has the text before, that is, to the left of, the text matched by the last pattern search. `RegExp.leftContext` is equivalent to `RegExp["$`"]`, for compatibility with PERL.

Read-only property.

SEE: [RegExp.lastMatch](#), [RegExp.rightContext](#)

EXAMPLE: 

```
var str = "one two three two one";
var pat = /(t.o)/
pat.exec(str);
// RegExp.leftContext == "one "
```

---

## RegExp.rightContext

---

SYNTAX: `RegExp.rightContext`

DESCRIPTION: This property has the text after, that is, to the right of, the text matched by the last pattern search. `RegExp.rightContext` is equivalent to `RegExp["$'"]`, for compatibility with PERL.

Read-only property.

SEE: [RegExp.lastMatch](#), [RegExp.leftContext](#)

EXAMPLE: 

```
var str = "one two three two one";
var pat = /(t.o)/
pat.exec(str);
// RegExp.rightContext == " three two one"
```

---

---

# SElib Object

The methods in the SElib object extend the functionality of JavaScript. Whereas the **Clib object** extends the power of JavaScript by providing functions from the standard C library, the SElib extends power by allowing programmers to work with such things as directories, files, memory, windows, messages, system operations, and script execution. The methods in the SElib object are more like the C functions in the Clib object than JavaScript functions.

When using the methods in this section, they are preceded with the Object name SElib, since individual instances of the SElib object are not created. For example, `SElib.directory()` is the syntax to use to get directory information in a script.

## SElib object static methods

---

### SElib.baseWindowFunction()

SYNTAX:	<code>SElib.baseWindowFunction(hWnd, message, param1, param2)</code>
WHERE:	<code>hWnd</code> - a number, a handle of the window receiving the message. <code>message</code> - a number, a Windows message ID. <code>param1</code> - the first parameter of the message ID. <code>param2</code> - the second parameter of the message ID.
RETURN:	<code>value</code> - the value returned by the base window function. If the parameter <code>handle</code> is not a window with a <code>windowFunction</code> created with <code>SElib.makeWindow()</code> or is not a window subclassed with <code>SElib.subclassWindow()</code> , then the return is 0.
DESCRIPTION:	Calls the base procedure of a window created with a <code>windowFunction</code> in <code>SElib.makeWindow()</code> or subclassed with <code>SElib.subclassWindow()</code> . This method is normally used within a ScriptEase window function to pass the window parameter to the base procedure before handling it in your own code. Remember that if your window function returns no value, ScriptEase will call the base procedure automatically, which is the preferred method.
SEE:	<a href="#">SElib.makeWindow()</a> , <a href="#">SElib.subclassWindow()</a> , Window object in <i>winobj.jsh</i>

---

### SElib.bound()

SYNTAX:	<code>SElib.bound()</code>
RETURN:	boolean - true if the currently running script is bound using the <code>/bind</code> command line option, else false.
DESCRIPTION:	ScriptEase scripts may be compiled to standalone executable, exe, files using the <code>bind</code> command line option. Sometimes it is

---

---

important to know if a script is being interpreted or being run as a standalone executable. Binding a script is a step more than compiling a script to be interpreted by a ScriptEase interpreter. (See [SElib.compileScript\(\)](#))

SEE: [SElib.compileScript\(\)](#), [SElib.version\(\)](#), Using Library Files

EXAMPLE:

```
if (SElib.bound())
{
    Screen.writeln('Running a bound script');
    // Do this
}
else
{
    Screen.writeln('Running an unbound script');
    // Do that
}
```

---

### **SElib.breakWindow()**

---

SYNTAX: `SElib.breakWindow(hWnd)`

WHERE: `hWnd` - a number, the handle of the window being released or destroyed.

RETURN: boolean - `true` on success and the window is successfully destroyed, released, or subclassed, else `false` on failure.

DESCRIPTION: For Win32 and Win16

Releases control of a window controlled by [SElib.subclassWindow\(\)](#) or destroys a window previously created with [SElib.makeWindow\(\)](#). No other windows are affected. If `hWnd` is not a valid window handle, no action is taken and `true` is returned.

When a window is destroyed all appropriate *DestroyWindow()* functions, internal to the Windows API, are called. Any child windows of a main window are destroyed before the main window.

If `hWnd` is a window controlled by [SElib.subclassWindow\(\)](#), then this method removes the WindowFunction for a window from the message function loop.

If `hWnd` is not supplied, then all windows created with `SElib.makeWindow()` are destroyed and all subclassing ends.

SEE: [SElib.makeWindow\(\)](#)

---

### **SElib.compileScript()**

---

SYNTAX: `SElib.compileScript(codeToCompile[, isFile])`

WHERE: `codeToCompile` - a string with ScriptEase statements or a filename of a script file.

`isFile` - a boolean telling whether or not `codeToCompile` is a filename or a string with statements. The default is `false` indicating that `codeToCompile` is a string consisting of

---

---

ScriptEase statements.

RETURN: buffer - the compiled code in a ScriptEase buffer. Normally, this buffer of compiled code is saved to a file.

DESCRIPTION: Compiles a ScriptEase script into executable code which is normally written to a file with an extension of ".jsb" and referred to as a ScriptEase binary file. This compiled code is the same code that is created when the /bind option is used with the Pro version of ScriptEase Desktop and the code is bound in an executable ".exe" file.

Compiled code may be executed in two ways. First, the compiled code may be passed to the `SElib.interpret()` method as the Code parameter. The `SElib.interpret()` method executes compiled code in the same way that it does text script. Second, a ScriptEase binary file may be executed by a ScriptEase interpreter, such as `sewin32.exe`. This second way is the most common way to execute compiled code. There are three basic ways that a ScriptEase script file may be run:

- A text script, as typed by a programmer, may be called using an interpreter program, such as `sewin32.exe`. The interpreter reads the text and performs all the statements in it. Running a script in this way results in the slowest overall execution speed since the interpreter must preprocess, tokenize, and run the file.
- A text script may be compiled using the `SElib.compileScript()` method and written to a ScriptEase binary file. A ScriptEase binary file may also be called by an interpreter program, such as `sewin32.exe`. But overall execution time is faster since the first two steps, preprocessing and tokenizing, are already done by `SElib.compileScript()`. The compiled code of a script is the same as the compiled code of an executable file produced using the /bind option of the Pro version.
- A text script can be compiled using the /bind option of the Pro version. The script is compiled, into the same form as when using `SElib.compileScript()` but is physically attached to the pertinent executable part of an interpreter, such as `sewin32.exe`. The compiled file is an executable file with an extension of ".exe" and can be run as a stand-alone program.

See the section on running a script in the manual or help file for more information on executing ScriptEase scripts.

ScriptEase binary files are called in the same way as text scripts, either ".jse" or ".jsh" files. Assume that a file named `testobj.jse` has been compiled with `SElib.compileScript()` to `testobj.jsb`. The invocations of either file by an interpreter do the same thing. For example, both lines below accomplish the same

---

---

thing when run as a command line.

```
sewin32.exe testobj.jse sewin32.exe testobj.jsb
```

The second line using ".jsb" executes faster, in overall time, that is, it begins executing more quickly.

In a like manner, assume that a file named testinc.jsh has been compiled with `SElib.compileScript()` to testinc.jsb. Either file may be included in a script using the preprocessor directive `#include`. Both lines of script below accomplish the same thing.

```
#include "testinc.jsh" #include "testinc.jsb"
```

The second line executes faster since the code in that file is precompiled. This include example points to another difference between the `/bind` option and the `SElib.compileScript()` method. The `/bind` option results in a stand-alone executable file. The `SElib.compileScript()` method allows the flexibility of precompiling sections of code that may be used in other scripts or of having a complete precompiled program. Complete programs compiled by either method execute at the same speed, at actual run time.

A compiled ScriptEase binary file may also be run from a script by using the `SElib.interpret()` method, using the `INTERP_COMPILED_SCRIPT` flag.

A ScriptEase binary file has 4 bits that identify it as a compiled script and 16 bytes for a checksum to make sure that the file has not been altered. Compiled scripts are implemented at a very low level which allows ScriptEase binary files to be included in a script, as already described. But, there is another benefit. A programmer may use file extensions other than the default ".jsb".

ScriptEase comes with a script, `compile.jse`, which automates the process of compiling a text script to a ScriptEase binary file.

SEE: [SElib.interpret\(\)](#), [SElib.interpretInNewThread\(\)](#), [SElib.bound\(\)](#), [sebind.jse](#), [compile.jse](#)

EXAMPLE:

```
// Compile the script file, myscript.jse,
// to the ScriptEase
// binary file, myscript.jsb.
function main(argc, argv)
{
    // Filename of the script to compile
    var infile = "Myscript.jse";
    // Filename for the compiled code
    var outfile = "Myscript.jsb";

    // Compile the script file
    // into compiled code.
    // Argument true indicates that infile is a
    filename
    var compiledScript = SElib.compileScript(infile,
true);
```

---

```

        // If the returned buffer has code in it,
        // save it to a file.
        if( compiledScript != null )
        {
            var outfp = Clib.fopen(outfile, "w");
            if( outfp == null )
            {
                Clib.fprintf(stderr,
                    "Could not open file \"%s\"\n",
                    outfile);
                Clib.fclose(outfp);
            }
            else
            {
                Clib.fwrite(compiledScript,
                    getArrayLength(compiledScript), outfp);
                Clib.fclose(outfp);
            }
        }
    }
}

```

---

## SElib.directory()

**SYNTAX:** SElib.directory([filespec[, subdirs[, includeAttr[, requireAttr]]]])

**WHERE:** filespec - string specification for files to find. The specification must be consistent with the operating system being used and may include wildcard characters. A file specification may include path specifications, both full and partial.

subdirs - a boolean as to whether or not to include subdirectories in file search. The default is `false`, which limits the search for filespec to the current directory.

includeAttr - specify the file attributes to include in the file search. Only files with one of the attributes specified will be included in the array of file names and information retrieved. Attribute flags that do not apply to an operating system are ignored. If includeAttr is 0, only files with no attributes are included. The default value is:

```
FATTR_RDONLY|FATTR_SUBDIR|
FATTR_ARCHIVE|FATTR_NORMAL
```

File attributes are set using the following values:

```
FATTR_RDONLY    Read-only file
FATTR_HIDDEN    Hidden file
FATTR_SYSTEM    System file
FATTR_SUBDIR    Directory
FATTR_ARCHIVE    Archive file
```

More than one file attribute can be specified by using the bitwise or operator, "|". For example, to find files with the hidden or system attributes set, use the following expression:

```
FATTR_HIDDEN | FATTR_SYSTEM
```

A file attribute may be excluded from array of files returned by using the bitwise not operator, "~". For example, to exclude

---

---

subdirectories, use the following expression:

```
~FATTR_SUBDIR
```

requireAttr - specify attributes that files are required to have to be included in the array of file names and information retrieved. Files must have at least these attributes. The difference between the two file attributes specifications is that files must have at least one of the attributes specified by includeAttr but must have all the attributes specified by requireAttr. The default value is 0.

RETURN:

array - an array of objects with information about the file names retrieved. If no files or directories match the specifications of the parameters, a null is returned. Each element of the array has the following properties:

```
.name      Full file name, including filespec path.
.attrib    File flags, as defined in IncAttr, number.
.size      Size of file, number in bytes, number.
.access    Date and time of last file access, number.
.write     Date and time of last write, number.
.create    Date and time of file creation, number.
```

For example, if you use the following line of code:

```
var FileList = SELib.directory("*.");
```

The information for the first file retrieved is accessed using:

```
FileList[0].name
FileList[0].attrib
FileList[0].size
FileList[0].access
FileList[0].write
FileList[0].create
```

The information for the second file is accessed using:

```
FileList[1].name
...
```

DESCRIPTION:

Find files in a directory

or subtree that match path and file specifications and have specified file attributes set. Remember the directory names are treated like file names and have the FATTR\_SUBDIR attribute set. Matching files and information about them are retrieved and returned in an array of objects. These objects are also structures.

This method may be used in many ways. One way, besides the obvious way of getting information about files, is to test for the existence of a file or file specification. If the file specified does not exist, the return is null.

SEE:

[SELib.fullpath\(\)](#), [SELib.splitFilename\(\)](#), File object in *fileobj.js*

EXAMPLE:

```
// The following routine lists
// all files matching FileSpec,
// except subdirectory entries,
// in the current directory of a script.
function ListDirectory(FileSpec)
```

---

---

```

{
    var FileList = SELib.directory(FileSpec, False,
    ~FATTR_SUBDIR)
    if (null == FileList)
        Clib.printf(
            "No files found for search spec \"%s\".\n",
            FileSpec)
    else
    {
        var FileCount = getArrayLength(FileList);
        for (var i = 0; i < FileCount; i++)
            Clib.printf(
                "%s\tsize = %d\tCreate date/time = %s\n",
                FileList[i].name, FileList[i].size,
                Clib.ctime(FileList[i].Create));
    }
}

```

---

## SElib.doWindows()

---

SYNTAX: `SElib.doWindows(immediateReturn)`

WHERE: `immediateReturn` - if `true` return immediately, regardless of messages. Default is `false`.

RETURN: `boolean` - `true` if any of the windows created with `SElib.makeWindow()` or subclassed with `SElib.subclassWindow()` are still open, that is, have not received a `WM_NCDESTROY` message. Returns `false` if there are no valid windows registered with the ScriptEase Window Manager.

DESCRIPTION: For Win32 and Win16

Starts the ScriptEase Window Manager to activate whatever windows have been created or subclassed with `SElib.makeWindow()` or `SElib.subclassWindow()`. All such windows are registered with the Window Manager. The Window Manager controls the messages sent to the windows in its registry and routes them to their respective window functions.

There should not be more than one copy of the Window Manager running at a time. Generally, `SElib.doWindows()` is called only once with a succession of windows. All windows created or subclassed after a call to `SElib.doWindows()` are automatically registered with the Window Manager.

The flags that define window messages are kept in the library file, `message.jsh`.

If the optional parameter `immediateReturn` is `true`, the method returns immediately, regardless of whether there are messages for this application or not. Otherwise this method yields control to other applications until a message has been processed, subject to filtering by `SElib.messageFilter()`, for this application or for any window subclassed by this application.

The example below displays a standard Windows window. If you click anywhere in the window, the string "You clicked me!"

---

---

is displayed briefly in the middle of the window. When the window is closed, the script terminates.

SEE: [SElib.makeWindow\(\)](#), [SElib.subclassWindow\(\)](#), Window object in *winobj.jsh*

EXAMPLE:

```
#include <message.jsh>
#include <window.jsh>
function main()
{
    var hWnd = SElib.makeWindow(null, null,
        WindowFunction, "Display Windows' messages",
        WS_OVERLAPPEDWINDOW | WS_VISIBLE,
        CW_USEDEFAULT, CW_USEDEFAULT,
        500, 350, null, 0);
    SElib.messageFilter(hWnd, WM_LBUTTONDOWN);
    while(SElib.doWindows()) ;
}

function WindowFunction(hWnd, msg, param1,
    param2, counter)
{
    if (msg == WM_LBUTTONDOWN)
    {
        var msgHwnd = SElib.makeWindow(hWnd,
            "static", null, "You clicked me!",
            WS_CHILD | WS_VISIBLE,
            200, 150, 100, 50, null, 0);
        SElib.suspend(1000);
        SElib.breakWindow(msgHwnd);
    }
}
```

---

## **SElib.fullpath()**

---

SYNTAX: `SElib.fullpath(pathspec)`

WHERE: `pathspec` - a partial path specification.

RETURN: string - the `pathspec` filled out to its full path specification or null if the path specification is invalid.

DESCRIPTION: Converts `pathspec` to a full and absolute path specification. The file name part of the path specification is not affected and may have wildcards. The drive and directory part of the path specification is converted or fleshed out to a full and absolute path.

The exact behavior of `SElib.fullpath()` depends on the underlying operating system. Some results can vary when using system specific path specifications.

SEE: [SElib.directory\(\)](#), [SElib.splitFilename\(\)](#), File object in *fileobj.jsh*

EXAMPLE:

```
// The following returns the full spec
// of current dir
function CurDir()
{
    return SElib.fullpath(".")
}

// The following returns the full spec
// of a parent dir
function CurDir()
```

---

---

```

    {
        return SElib.fullpath("../")
    }
    // The following works in DOS or OS/2
    // to test whether a drive
    // letter is valid
function ValidDrive(DriveLetter)
{
    Clib.sprintf(CurdirSpec, "%c:", DriveLetter)
    return (null != SElib.fullpath(CurdirSpec) )
}

```

---

## **SElib.getObjectProperties()**

---

**SYNTAX:** SElib.getObjectProperties(object[, includeUndefined])

**WHERE:** object - an object from which to get its properties.

includeUndefined - a boolean, determines whether or not to include properties with undefined values. The default is false, that is, do not include properties with undefined values.

**RETURN:** object - an array of strings which are the names of the properties of the object. The array is terminated with a null, that is, the last element is always null.

**DESCRIPTION:** Get the names of the properties of an object in an array of strings in which each element is a property name and the last element is null.

The parameter includeUndefined must be true to return properties that are not defined. If includeUndefined is false, then only properties that have defined data are included. The default for includeUndefined is false.

The final member of the returned array returned is always null. If the parameter object is not defined or contains no properties, then the return is an array with a single element set to null.

SElib.getObjectProperties() is similar to the ECMAScript **for/in** loop. The important difference is that a for/in loop does not enumerate properties that have DONT\_ENUM as part of their attributes (**global.setAttributes()**), whereas SElib.getObjectProperties() includes them in the array that it returns.

**SEE:** [for/in, Object.prototype.isEnumerable\(\)](#)

**EXAMPLE:**

```

var Point;
Point.row = 5;
Point.col = 8;
Point.height;
DisplayAllStructureMembers(Point);

function DisplayAllStructureMembers(ObjectVar)
{
    Screen.writeln("Object Properties:");
    var MemberList =

```

---

---

```
SElib.getObjectProperties(ObjectVar);
    for (var i = 0; MemberList[i]; i++)
        Clib.printf(" %s\n", MemberList[i]);
}

// This fragment produces the following output.
// Object Properties:
//   row
//   col
```

---

### **SElib.inSecurity()**

---

**SYNTAX:** SElib.inSecurity(infoVar)

**WHERE:** infoVar - variable to be passed to the ScriptEase security filter. Your application and its security filter may use it however you choose.

**RETURN:** boolean - true if there is a security filter, else false.

**DESCRIPTION:** Calls the security manager's initialization routine and is the only way your application can directly interact with the security filter. It is provided so you can reinitialize the security system, probably to change the security level of a script.

Typically, you use this method when executing a particularly insecure piece of code, such as a script received over a network, to downgrade the security level, restoring it when the script completes.

---

### **SElib.instance()**

---

**SYNTAX:** SElib.instance()

**RETURN:** number - instance handle of the current ScriptEase session, that is, for the current script.

**DESCRIPTION:** For Win32

Get the instance handle of the currently executing script. This handle may be used with Windows API functions that use an instance handle.

**SEE:** Screen.handle(), SElib.makeWindow(), icon.jsh, pickfile.jsh, dropper.jse, iconmany.jse

**EXAMPLE:** var hScript = SElib.instance()

---

### **SElib.interpret()**

---

**SYNTAX:** SElib.interpret(codeToInterpret[, howToInterpret[, security]])

**WHERE:** codeToInterpret - a string with ScriptEase code statements to be interpreted as script statements or the file specification, path and file name, of a script file. If the interpreted code receives arguments, they are put at the end of the codeToInterpret string--somewhat like a command line string.

howToInterpret - tells how to handle the interpreted code. The following flag values may be combined using the bitwise or

---

---

operator, "|". The value must be 0 or one of the following choices:

- `INTERP_FILE`  
CodeToInterpret is the file name of a script, followed by any arguments.
- `INTERP_TEXT`  
CodeToInterpret is a string of source code with no arguments attached.
- `INTERP_LOAD`  
Load code into same function and variable space as the script that is calling `SElib.interpret()`. All functions, and variables are supplied to the code being called, which can modify and use them. If the code being called has similarly named functions or variables as the calling code, functions in the called code replace those in the calling code.
- `INTERP_NOINHERIT_LOCAL`  
Local variables are not inherited by the interpreted code.
- `INTERP_NOINHERIT_GLOBAL`  
Global variables are not inherited by the interpreted code as globals.
- `INTERP_COMPILED_SCRIPT`  
Run a script compiled with `SElib.compileScript()`. This flag only works with the `INTERP_TEXT` flag.

`INTERP_FILE` and `INTERP_TEXT` are mutually exclusive. If neither is supplied the interpreter decides whether `codeToInterpret` is a file or string of code.

These flags tell the computer how to interpret the parameter `codeToInterpret`. If one is not supplied, the computer parses the string and determines the most appropriate way to interpret it.

`security` – the filename of the security script to run this interpreted script using. This is exactly like the security script passed to `SEdesk` using the `"/secure="` option, except it applies only to the script you are about to interpret. Remember that security is additive; any existing security is still in effect for the interpreted script as well.

RETURN: value - the return of the interpreted code.

DESCRIPTION: Interprets a string as if it were script. More flexible than the JavaScript `global.eval()` function since it interprets a file as well as a string and allows more control over how interpreted code inherits variables from the script that calls `SElib.interpret()`. By default, all variables in a script are inherited as global variables.

There is no specific return for an error. To trap an error use the `try/catch` error trapping statements.

The `SElib.interpret()` method may not be used with scripts

---

---

that have been compiled into executable files using the `/bind` option of the Pro version of ScriptEase Desktop.

SEE: [SElib.interpretInNewThread\(\)](#), [SElib.spawn\(\)](#)

EXAMPLE: 

```
// The following interpreted code displays "Hello
world"
SElib.interpret('Screen.writeln("Hello world"',
INTERP_TEXT);
// The following interprets
// the file jseedit.jse with
// autoexec.bat as an argument to the script
SElib.interpret("jseedit.jse c:\\autoexec.bat",
INTERP_FILE);
```

---

## **SElib.interpretInNewThread()**

---

SYNTAX: `SElib.interpretInNewThread(filename, codeToInterpret)`

WHERE: `filename` - the name of a script file with ScriptEase code. Use `null` if not interpreting a file.

`codeToInterpret` - a string variable with one or more ScriptEase statements to interpret, if not using a file. If a file is being interpreted, the string is used as command line arguments for the script file being interpreted.

RETURN: `number` - the ID of the thread containing the new instance of ScriptEase. Depending on the operating system, returns 0 or -1 on an error.

DESCRIPTION: For Win32 and OS/2, that is, for operating systems that support multithreading. Not supported for operating systems that do not support multithreading, such as DOS and 16-bit Windows.

This method creates a new thread within the current ScriptEase process and interprets a script within that new thread. The new script runs independently of the currently executing thread. This method differs from [SElib.interpret\(\)](#) in that the calling thread does not wait for the interpretation to finish and differs from [SElib.spawn\(\)](#) in that the new thread runs in the same memory and process space as the currently running thread.

A script writer must ensure any synchronization among threads. ScriptEase data and globals are on a per-thread basis.

If the parameter `filename` is not `null`, then it is the name of a file to interpret, and the parameters, `filename` and `codeToInterpret` are parsed as if being command line parameters to a `main()` function.

If the parameter `filename` is `null`, then `codeToInterpret` is treated as JavaScript code, a string with ScriptEase statements, and is interpreted directly.

SEE: [SElib.interpret\(\)](#), [SElib.spawn\(\)](#)

EXAMPLE: 

```
// See usage in threads.jse and httpd.jse
```

---

## SElib.makeWindow()

---

SYNTAX: SElib.makeWindow(parent, class, windowFunction,  
text, style, col, row,  
width, height,  
createParam, utilityVar)

WHERE: parent - window handle of the parent window of this window, which would mean that this window is a subwindow. Pass `null` if this window is being created on the desktop, without a specific window being its parent. If `null`, the desktop is the parent.

class - a string or an object. If this parameter is a string, it must be one of the pre-existing Windows classes:

```
button  
combobox  
edit  
listbox  
scrollbar  
static
```

If this parameter is an object or structure it may have the following properties:

```
.style           Windows class style  
.icon            icon bitmap for minimized window  
.cursor         appearance when over this window  
.background     window background color
```

Properties that are not assigned values receive default values. In general, the class defines the behavior of a window.

windowFunction - an identifier, the function that is called whenever Windows sends a message to this window. Use `null` if no function is to be called to intercept windows messages. In the case of `null`, default functions for Windows are called. If specified, the windowFunction should return a number or nothing. Use the actual identifier of the function and not a string with its name. For example, use `MyWinFunction` instead of `"MyWinFunction"`. The windowFunction is described in greater detail in the description section.

text - the window title or caption that appears in the title bar. Use `null` or `""` if the window has no title.

style - the style of the window. Windows has many predefined styles that may be joined into one style by using the bitwise or operator, `|`. Windows styles are defined with `"WS_"` at the beginning. For example, `WS_MAXIMIZEBOX | WS_THICKFRAME` would define a window that has a thick frame and a maximize box. The `"WS_"` windows styles are standard definitions used in Windows programming and may be found in `winobj.jsh` or `window.jsh`.

col - the left most column of the window, expressed in pixels.

row - the top most row of the window, expressed in pixels.

Together, col and row define the top left corner of the window.

---

---

Use `CW_USEDEFAULT` for col and row to let Windows set the position.

width - the total width of the window, expressed in pixels.

height - the total height of the window, expressed in pixels. By using col, row, width, and height, a window can be placed precisely on a screen.

createParam - normally set to `null`. If used, it may be a number or object that is passed with the Windows `WM_CREATE` message when creating a window.

utilityVar - any variable that a scripter chooses. This variable is passed to the windowFunction when it receives a Windows message. The windowFunction may alter the utilityVar. An object or structure may be used, in which case many values may be passed and altered as properties of the object. One practice is to use an object to keep up with the properties of a window, sometimes including its subwindows. This object is a good vehicle for passing information.

RETURN: number - the handle of the window created on success, else `null`.

DESCRIPTION: For Win32 and Win16

This method is the basic function for creating windows that will be opened and managed by ScriptEase. This function provides the basis for normal windows operations when windows created by it are opened. This function registers the created window with ScriptEase, so that when the `.doWindows()` method is executed, this window will be properly managed.

If the class of the Window is unknown, it is registered as a new class.

The windowFunction, a parameter of `SElib.makeWindow()`, is a function that is specified to intercept and handle all Windows messages that are posted to this window, the window just created by `SElib.makeWindow()`. The windowFunction will intercept all messages sent its associated window which slows execution of a script. Use `SElib.messageFilter()` to limit the messages that are actually intercepted by the windowFunction. If the windowFunction has a return value, it must be a number, which seems limiting. But remember, that you may use utilityVar as a variable for receiving information and for passing information.

The definition of a windowFunction must follow the following format:

```
function MyWinFunction(hWnd, Message, Param1,
                        Param2 [, utilityVar])
{
// Body of the window function
}
```

---

**hWnd** - a number, Window handle for the window that receives these Windows messages. It is the handle of the window created by `SElib.makeWindow()` that specified this function to receive messages.

**Message** - a number, a message ID. Windows defines message IDs and posts them to windows.

**Param1** - a parameter that may accompany a message.

**Param2** - a second parameter that may accompany a message.

**utilityVar** - an optional variable that is specified in the `SElib.makeWindow()` call that created this window. This variable is often an object/structure with several pieces of information which may be altered. If it is, the changes are available to other functions that may use the variable while `SElib.doWindows()` is active and is showing and managing the windows under its control.

SEE: [SElib.doWindows\(\)](#)

EXAMPLE:

```
var InfoStruct;
InfoStruct.width = 400;
InfoStruct.height = 300;

var hWnd = SElib.makeWindow
(
    0, null, MyWinFunction,
    "My Window", WS_MAXIMIZEBOX,
    CW_USEDEFAULT, CW_USEDEFAULT,
    InfoStruct.width, InfoStruct.height,
    null, InfoStruct
);

function MyWinFunction(hWnd, Msg, Param1,
                        Param2, UtilVar)
{
    // Body of function to process messages.
    // Notice that UtilVar receives InfoStruct
}
```

---

## **SElib.messageFilter()**

---

SYNTAX: `SElib.messageFilter(hWnd[, message[, ...]])`

WHERE: **hWnd** - a number, the handle of a window created by `SElib.makeWindow()` or subclassed with `SElib.subclassWindow()`.

**message** - one or more messages to be processed by the window to which **hWnd** points.

RETURN: **object** - an array of messages being filtered prior to this call to `SElib.messageFilter()`. Returns `null` if no messages are in the filter, that is, all messages are passed through to ScriptEase functions or if **hWnd** is not a handle for a window processed by `SElib.makeWindow()` or `SElib.subclassWindow()`.

DESCRIPTION: For Win32 and Win16

---

---

Restricts the messages being processed by windows created with `SElib.makeWindow()` or subclassed with `SElib.subclassWindow()`. Scripts run much faster if windows only process the messages that they act on, that is, just the messages that they need. Initially, there are no message filters so all messages are processed.

Calling this method with no parameters removes all message filtering.

SEE: [SElib.makeWindow\(\)](#), [SElib.subclassWindow\(\)](#)

---

### **SElib.multiTask()**

---

SYNTAX: `SElib.multiTask(on)`

WHERE: `on` - a boolean determining whether multitasking is on or off. Default is `true`.

RETURN: `void`.

DESCRIPTION: For Win16

Turns multitasking of programs on or off. Normally, multitasking is enabled and should be turned off only for very brief and critical sections of code. No messages are received by the current program or any other program while multitasking is off.

`SElib.multiTask()` is additive, meaning that if you call `SElib.multiTask(false)` twice, then you must call `SElib.multiTask(true)` twice before multitasking is resumed.

The example below empties the clipboard. Multitasking is turned off during this brief interval to ensure that no other program tries to open the clipboard while this program is accessing it.

SEE: [SElib.suspend\(\)](#)

EXAMPLE: 

```
SElib.multiTask(false);
SElib.dynamicLink("USER", "OPENCLIPBOARD", SWORD16,
                  PASCAL, Screen.handle());
SElib.dynamicLink("USER", "EMPTYCLIPBOARD", SWORD16,
                  PASCAL);
SElib.dynamicLink("USER", "CLOSECLIPBOARD", SWORD16,
                  PASCAL);
SElib.multiTask(true);
```

---

### **SElib.peek()**

---

SYNTAX: `SElib.peek(address[, dataType])`

WHERE: `address` - the address in memory from which to get data, that is, a pointer to data in memory.

`dataType` - the type of data to get, or thought of in another way, the number of bytes of data to get. `UWORD8` is the default.

RETURN: `value` - returns the data specified by `dataType`

---

---

DESCRIPTION: Reads or gets data from the position in memory to which the parameter address points. The parameter dataType may have the following values:

UWORD8    SWORD8    UWORD16    SWORD16    UWORD24  
SWORD24   UWORD32   SWORD32    FLOAT32    FLOAT64  
FLOAT80   (FLOAT80 is not available in Win32)

These values specify the number of bytes to be read and returned.

Caution. Routines that work with memory directly, such as this one, should be used with caution. A programmer should clearly understand memory and the operations of these methods before using them. ScriptEase does not trap errors caused by this routine.

SEE: [SElib.poke\(\)](#), [Blob.get\(\)](#), [Clib.memchr\(\)](#), [Clib.fread\(\)](#)

EXAMPLE:

```
var v = "Now";  
    // Display "Now"  
Screen.writeln(v);  
    // Get the "N"  
var vPtr = SElib.pointer(v);  
    // Get the address of the first byte of v, "N"  
var p = SElib.peek(vPtr);  
    // Convert "N" to "P"  
SElib.poke(vPtr,p+2);  
    // Display "Pow"  
Screen.writeln(v);  
  
// See usage in clipbrd.jsh, com.jsh,  
// dde.jsh, ddesrv.jsh, and winsock.jsh
```

---

## **SElib.pointer()**

---

SYNTAX: `SElib.pointer(varName)`

WHERE: `varName` - the name or identifier of a variable

RETURN: number - the address of, a pointer to, the variable identified by `varName`.

DESCRIPTION: Gets the address in memory of a variable. The pointer points to the first byte of data in a variable. The variable may be a primitive data type: byte, integer, or float, or it may be a single dimension array of bytes, integers, or floats, which includes a string. If the variable is an array, then the address returned points to the first byte of the first element of the array. The parameter `varName` may also identify a Blob variable since Blobs are actually byte arrays. Other types of data are not allowed.

For computer architectures that distinguish between near and far memory addresses, the value returned by `SElib.pointer()` is a far address or pointer.

ScriptEase data is guaranteed to remain fixed at its memory location only as long as that memory is not modified by a script. Thus, a pointer is valid only until a script modifies the variable identified by `varName` or until the variable goes out of scope in a

---

---

script. Putting data in the memory occupied by varName after such a change is dangerous. When data is put into the memory occupied by varName, be careful not to put more data than will fit in the memory that the variable actually occupies.

Caution. Routines that work with memory directly, such as this one, should be used with caution. A programmer should clearly understand memory and the operations of these methods before using them. ScriptEase does not trap errors caused by this routine.

SEE: [SElib.peek\(\)](#), [SElib.poke\(\)](#), [Clib.memchr\(\)](#), [Blob object](#)

EXAMPLE:

```
var v = "Now";
    // Display "Now"
Screen.writeln(v);
    // Get the "N"
var vPtr = SElib.pointer(v);
    // Get the address of the first byte of v, "N"
var p = SElib.peek(vPtr);
    // Convert "N" to "P"
SElib.poke(vPtr,p+2);
    // Display "Pow"
Screen.writeln(v);

// See usage in fileobj.jsh, batch.jsh,
// memsrch.jsh, touch.jsh, and pickfile.jsh
```

---

## **SElib.poke()**

---

SYNTAX: `SElib.poke(address, data[, dataType])`

WHERE: address - the address in memory in which to put data, that is, a pointer to data in memory.

data - data to write directly to memory. The data should match the dataType.

dataType - the type of data to get, or thought of in another way, the number of bytes of data to get. UWORD8 is the default.

RETURN: number - the address of the byte after the data just written to memory.

DESCRIPTION: Writes data to the position in memory to which the parameter address points. The data to be written must match the dataType. The parameter dataType may have the following values:

```
UWORD8   SWORD8   UWORD16  SWORD16   UWORD24
SWORD24  UWORD32  SWORD32   FLOAT32   FLOAT64
FLOAT80  (FLOAT80 is not available in Win32)
```

These values specify the number of bytes to be written to memory.

Caution. Routines that work with memory directly, such as this one, should be used with caution. A programmer should clearly understand memory and the operations of these methods before using them. ScriptEase does not trap errors caused by this

---

---

routine.

SEE: [SElib.peek\(\)](#), [Blob.put\(\)](#), [Clib.memchr\(\)](#), [Clib.fread\(\)](#)

EXAMPLE:

```
var v = "Now";
// Display "Now"
Screen.writeln(v);
// Get the "N"
var vPtr = SElib.pointer(v);
// Get the address of the first byte of v, "N"
var p = SElib.peek(vPtr);
// Convert "N" to "P"
SElib.poke(vPtr,p+2);
// Display "Pow"
Screen.writeln(v);

// See usage in bmp.jsh, clipbrd.jsh,
// dde.jsh, ddecli.jsh, and dropsrc.jsh
```

---

## **SElib.ShellFilterCharacter()**

---

SYNTAX: `SElib.ShellFilterCharacter(functionFilterCharacter, allKeys)`

WHERE: `functionFilterCharacter` - identifier, the name of a `ScriptEase` function to use to filter characters.

`allKeys` - boolean, specifies whether the `functionFilterCharacter` is called for every keystroke or just for keys that are not ordinary printable characters, such as function keys. The return of the method [Clib.isprint\(\)](#) corresponds to the difference in keys that `allKeys` affects.

RETURN: `void`.

DESCRIPTION: Adds a character filter function to a `ScriptEase` shell. When `ScriptEase` is running as a command shell, that is, when a `ScriptEase` interpreter is executed with no arguments, this method allows the installation of a function to be called when keystrokes are pressed. For example, the `autoload.jse` script that ships with `ScriptEase` uses this method to implement command line history and filename completion.

The function, `functionFilterCharacter`, must conform to the following:

```
function functionFilterCharacter(command,
    position, key, extended, alphaNumeric)
```

`command` - string, the current string on the shell command line. This string is read/write and may be changed by this function.

`position` - number, the current cursor position within the command string. This position may be altered by this function.

`key` - number, the key being pressed. This parameter may be altered by the function. Set `key` to zero, 0, to ignore keyboard input.

`extended` - boolean, `true` if the current keystroke is an extended keyboard character, that is, a function key, a keyboard combination,

---

---

and so forth.

alphaNumeric - `true` if the current keystroke is an alphabetic or numeric key. The return of the method `SElib.isalnum()` corresponds to alphaNumeric.

return - boolean, `true` if the command line must be redrawn or the cursor position moved, based on the actions in this function.

SEE: [SElib.ShellFilterCommand\(\)](#), [SElib.isalnum\(\)](#), [autoload.jse](#)

---

## **SElib.ShellFilterCommand()**

---

SYNTAX: `SElib.ShellFilterCommand(functionFilterCommand)`

WHERE: `functionFilterCommand` - identifier, the name of a function to use to filter commands to a ScriptEase shell.

RETURN: `void`.

DESCRIPTION: Adds a command filter function to a ScriptEase shell. When ScriptEase is running as a command shell, that is, when a ScriptEase interpreter is executed with no arguments, this method allows a function to be installed which is called when commands are entered in a shell. For example, the `autoload.jse` script that ships with ScriptEase uses this method to implement commands, such as `CD` and `TYPE`.

The function, `functionFilterCommand`, must conform to the following:

```
function functionFilterCommand(command)
```

`command` - a string, the current string on a shell command line. This string is read/write and may be changed by the function. A ScriptEase shell executes the command after returning from this function. To prevent ScriptEase from executing any command set `command` to a zero-length string, for example, `command[0]='\0'`, but not `command=""`.

Before passing a command line to a filter function, ScriptEase strips leading white space from the beginning and end of the command string. Also, any redirection on a command line is not seen by this function, since redirection is handled internally by ScriptEase. For example, if a command line string is `"dir>dir.txt"`, then this function only sees the string `"dir"`.

SEE: [SElib.ShellFilterCommand\(\)](#), [autoload.jse](#)

---

## **SElib.spawn()**

---

SYNTAX: `SElib.spawn(mode, execSpec[, arg[, ...]])`

WHERE: `mode` - a number indicating how to spawn or execute the file named by `execSpec`. The parameter `mode` may be one of the following values though not all values are valid on all operating systems:

---

- 
- `P_WAIT` Wait for a child program to complete before continuing. (All platforms)
  - `P_NOWAIT` A script continues to run while a child program runs. In windows, a successful call with mode `P_NOWAIT` returns the window handle of the spawned process. (Windows and OS/2)
  - `P_SWAP` Like `P_WAIT`, but swap out ScriptEase to create more room for the child process. `P_SWAP` will free up as much memory as possible by swapping ScriptEase to *EMS/XMS/INT15* memory or to disk (in *TMP* or *TEMP* or else current directory) before executing the child process (thanks to Ralf Brown for his excellent spawn library). (DOS only)
  - `P_OVERLAY` The script exits and the child program is executed in its place. (DOS 16-bit)

`execSpec` - a string with the path and filename of an executable file or a ScriptEase script.

`arg` - one or more values to be passed as parameters to the file to be executed.

RETURN: void - if the mode is `P_OVERLAY`.

number - if the mode is `P_WAIT`, the return is the exit code of the child process, else it is -1.

number - if the mode is `P_NOWAIT` or `P_SWAP`, the return is the identifier of the child process, else it is -1.

DESCRIPTION: Launches another application. The parameter `mode` determines the behavior of the script after the spawn call, while `execSpec` is the name of the process being spawned. Any arguments to the spawned process follow `execSpec`.

The parameter `execSpec` may be the path and filename of an executable file or the name of a ScriptEase script. If it is a script, the spawned script runs from the same instance of ScriptEase as the calling script. A spawned script does not cause another instance of the interpreter to be launched. A script that has been bound with the ScriptEase `/bind` function cannot be spawned from the same instance as the calling script.

The parameter `execSpec` is automatically passed as argument 0. ScriptEase implicitly converts all arguments to strings before passing them to the child process.

`SElib.spawn()` searches for `execSpec` in the current directory and then in the directories of the `PATH` environment variable. If there is no extension in `execSpec`, `SElib.spawn()` searches for file extensions in the following order: `com`, `exe`, `bat`, and `cmd`.

If a batch file is being spawned in 16-bit DOS and the environment variable `COMSPEC_ENV_SIZE` exists, the command processor is provided the amount of memory as indicated by

---

---

COMSPEC\_ENV\_SIZE. If COMSPEC\_ENV\_SIZE does not exist, the command processor receives only enough memory for existing environment variables.

A return value of -1 results when **Clib.errno** is set to identify why the function failed.

SEE: [SElib.interpret\(\)](#), [SElib.interpretInNewThread\(\)](#), *winexec.jsh*

EXAMPLE:

```
// The following fragment
// calls a mortgage program,
// mortgage.exe, which takes
// three parameters, initial debt,
// rate, and monthly payment, and
// returns, in its exit code,
// the number of months needed to pay the debt.
var months = SElib.spawn(P_WAIT,
    "MORTGAGE.EXE 300000 10.5 1000");
if (months < 0)
    Screen.writeln( "Error spawning MORTGAGE");
else
    Clib.printf(
        "It takes %d months to pay off the mortgage\n",
        months);

// The arguments could also
// be passed to mortgage.exe as
// separate variables, as in the following.
var months = SElib.spawn(P_WAIT,
    "MORTGAGE.EXE", 300000, 10.5, 1000);

// The arguments could be passed
// to mortgage.exe in a
// variable array, provided that
// they are all of the same
// data type, in this case strings.
var MortgageData;
MortgageData[0] = "300000";
MortgageData[1] = "10.5";
MortgageData[2] = "1000";
var ths = spawn(P_WAIT,
    "MORTGAGE.EXE", MortgageData);
```

---

## **SElib.splitFilename()**

---

SYNTAX: `SElib.splitFilename(filespec)`

WHERE: `filespec` - string specification for a file. May be a full or partial path specification.

RETURN: object - structure containing the drive and directory, file, and extension information contained in `filespec`. The structure returned has the following properties:

```
.dir    directory name including leading drive
        spec and trailing slash (d:\dir1\dir2\)
.name   root name of file only (filename)
.ext    file extension with leading period (.ext)
```

The three properties returned are guaranteed not to be null.

The actual characters used, such as the slash, depend on the

---

---

operating system.

DESCRIPTION: Break up a file specification, full or partial path specification, into its component parts: drive and directory, filename, and extension. The filespec does not have to actually exist. This method merely divides up the filespec, as passed, according to the conventions of the operating system without checking to see if a drive, directory, or filename actually exists.

SEE: [SElib.fullpath\(\)](#), [File.splitName\(\)](#), File object in *fileobj.jsh*

EXAMPLE: 

```
// After splitting a filespec,
// the following statement will
// reconstruct it
var parts = SElib.splitFilename(MySpec);
var FileSpec = MySpec.dir + MySpec.name + MySpec.ext;
```

---

### **SElib.subclassWindow()**

---

SYNTAX: `SElib.subclassWindow(hWnd, windowFunction, utilityVar)`

WHERE: hWnd - a number, the handle of an existing window to subclass.

windowFunction - an identifier, the function that is called whenever Windows sends a message to this window. The parameter windowFunction is the same as for `SElib.makeWindow()`.

utilityVar - any variable that a scripter chooses. This variable is passed to the windowFunction when it receives a Windows message. The parameter utilityVar is the same as for `SElib.makeWindow()`.

RETURN: boolean - true on success, else false if hWnd is invalid, was created with `SElib.makeWindow()`, or is already subclassed.

DESCRIPTION: For Win32 and Win16

This method hooks the specified windowFunction into the message loop for a window such that the function is called before the window's default or previously-defined function.

The parameter hWnd is the window handle of an already existing window to subclass.

The parameter windowFunction is the same as in the [SElib.makeWindow\(\)](#) method. Note that, as in the `SElib.makeWindow()` method, if this method returns a value, then the default or subclassed function is not called. If this method returns no value, the call is passed on to the previous function. This method may be used to subclass any Window that is not already being managed by a windowFunction for this ScriptEase instance. If a window was created with `SElib.makeWindow()` or is already subclassed then this method fails.

Note that this method may be used only once, with the window handle returned by `Screen.handle()`. If you want to subclass the

---

---

main ScriptEase window, it is best to open another instance of ScriptEase and subclass it rather than to subclass the instance that is powering your script. Although it is possible to subclass that window, if you try to do anything with it, you will likely get caught in an infinite loop and hang. To undo the window subclassing or remove a WindowFunction from the message loop, use [SElib.breakWindow\(\)](#).

A WindowFunction may modify UtilityVar.

In your function that handles messages for another process, certain limits are set as to what you can do with system resources. For example, an open file handle is invalid while processing a message for another program, because Windows maps file handles into a table for programs. To work around this problem, you may send a message to one of your ScriptEase windows to handle the processing. This action switches Windows' tables to your program while handling that SendMessage.

SEE: [SElib.makeWindow\(\)](#), Window object in *winobj.jsh*

---

## **SElib.suspend()**

---

SYNTAX: `SElib.suspend(milliSeconds)`

WHERE: `milliSeconds` - a number, the time in thousandths of a second to suspend program execution.

RETURN: `void`.

DESCRIPTION: Suspends script or program execution for the time interval specified in `milliSeconds`. The next statement in a script will execute at the end of the delay.

True accuracy to the exact millisecond is not guaranteed and is only closely approximated according to the accuracy provided by the underlying operating system. This method allows a computer to devote more time to other processes and can be used to give the processor time to complete other tasks before calling the next line in a script.

The example below spawns a copy of Windows Notepad, puts the date and time into the document by simulating the selection of Time/Date from the Edit menu, and then displays the line "You asked for the time?". The `SElib.suspend()` method gives the processor time to finish completing the menu command before entering the text into Notepad. If `Keystroke()` were called immediately after the call to `MenuCommand()`, the text would be sent to Notepad while the menu item was still being selected and would be garbled.

SEE: [SElib.spawn\(\)](#), [Clib.ctime\(\)](#), [Date](#) object

EXAMPLE: 

```
#include <menuctrl.jsh>
#include <keypush.jsh>
var hWnd = SElib.spawn(P_NOWAIT, "notepad.exe");
```

---

---

```
MenuCommand(hWnd, "Edit|Time");
SElib.suspend(300);
KeyStroke("\nYou asked for the time?");
```

---

## **SElib.version()**

---

**SYNTAX:** SElib.version()

**RETURN:** object - an object with properties that provide information about the version and operating system of the currently executing ScriptEase interpreter. The object returned has the following properties:

```
.os - string, identifying operating system
.se.engineVersion - number, major minor version
.se.versionString - string, sub minor version
.buildTime - string, date/time of build
.bindable - boolean, can bind to executable
.security - boolean, uses security features
```

**DESCRIPTION:** This method provides a variety of useful information about the version of the currently executing ScriptEase interpreter.

The `.os` string will be something like:

```
DOS
DOS32
MAC
NWNLM
OS2
WINDOWS
WIN32.NTCON
WIN32.NTWIN
WIN32.95CON
WIN32.95WIN
UNIX
```

**SEE:** getSEver(), getSEversion(), predefined constants and values  
VERSION\_MAJOR, VERSION\_MINOR, VERSION\_STRING

**EXAMPLE:**

```
var ver;
ver = SElib.version();
Screen.writeln(ver.os);
Screen.writeln(ver.se.engineVersion);
Screen.writeln(ver.se.versionString);
Screen.writeln(ver.buildTime);
// Displays something like:
// WIN32.95CON
// 440
// B
// Apr 26 2001 16:06:49
```

---

## **SElib.windowList()**

---

**SYNTAX:** SElib.windowList(hWnd)

**WHERE:** hWnd - a number, the handle of the window for which to find its child windows.

**RETURN:** object - an array of window handles for all the child windows of hWnd.

**DESCRIPTION:** For Win32 and Win16

---

---

Get the handles of all child windows of the window designated by hWnd. If hWnd is not passed, then get the handles of the windows on the desktop which amount to all the parent windows.

SEE: [SElib.makeWindow\(\)](#), Window object in *winobj.jsh*

---

## **SElib.dynamicLink()**

**Dynamic links** for Win32, Win16, and OS/2

The dynamic link method, which varies in usage among the three platforms that support it, allows flexibility when making calls to dynamic link libraries, DLLs, and allows access to operating-system functions, API calls, not explicitly provided by ScriptEase. If you know the proper conventions for a call, then you can make an `SElib.dynamicLink()` call in a ScriptEase function to be used for making a system call. Such a function is referred to as a wrapper, a function in which a system call becomes available as a function call.

There are three versions of `SElib.dynamicLink()`: Win32, Win16, and OS/2. These three versions differ slightly in the way they are called. So, if you wish to use one function in a script that will be run on different platforms, you must create an operating system filter using preprocessor directives: `#if`, `#ifdef`, `#elif`, `#else`, and `#endif`.

Since these versions are different in the way that they call `SElib.dynamicLink()`, they will be treated separately.

See Win32 structure definitions.

### **SElib.dynamicLink() - for Win32**

---

**SYNTAX:** `SElib.dynamicLink(library, procedure, convention[, [desc,] param ...])`

**WHERE:** `library` - a string, the name of the dynamic link library, DLL, being used, the one having the procedure being called.

`procedure` - a string or number, the name or ordinal number of a routine in a dynamic link library to be used.

`convention` - the calling convention to use when invoking or using the procedure being called.

<code>CDECL</code>	Push right parameter first. Caller pops parameters.
<code>STDCALL</code>	Push right parameter first. Caller pops parameters.
<code>PASCAL</code>	Push left parameter first. Callee pops parameters.

`desc` - a blobDescriptor that describes the following param if param is a structure. (See [blobDescriptor example](#).) A blobDescriptor is only used in front of params that are structures and is required for such params. A Blob (Binary Large Object) and a Buffer are very similar in ScriptEase. The Blob is the type that was used, in the early days of ScriptEase, to work with data in sections of memory. The Buffer is the newer type. Structure types may be created in Blobs or Buffers and blobDescriptors

---

---

may be used to describe the data in either type. So, in ScriptEase, you will sometimes see blobDescriptor before a param of type Blob or a param of type buffer. In either case, the blobDescriptor is describing how data is stored in the param, even if the data is a string.

param - a variable for a section of memory that holds data in the form of a structure of elements or a buffer a string.

RETURN: value - the value returned by the procedure being called, else void if the procedure does not return a value.

DESCRIPTION: For Win32

Calls a routine in a dynamic link library, DLL. The most common use is to use various functions in the Windows API.

All values are passed as 32-bit values. If a parameter is undefined when dynamicLink() is called, then it is assumed that the parameter is a 32-bit value to be filled in, that is, the address of a 32-bit data element is passed to the function, and that function will set the value.

If a parameter is a structure, then it must be a structure that defines the binary data types in memory to represent the following variable. Before calling the DLL function, the structure is copied to a binary buffer as described in [Blob.put\(\)](#) and [Clib.fwrite\(\)](#). When calling the DLL function, a descriptor argument must precede the structured parameter, and this descriptor argument is in addition to the parameter list for the procedure being called. After calling the DLL function, the binary data will be converted back into the data structure according to the rules defined in [Blob.get\(\)](#) and [Clib.fread\(\)](#). Data conversion is performed according to the current `_BigEndianMode` setting.

SEE: [Blob object](#), [blobDescriptor example](#), Win32 structure definitions, [Clib.fread\(\)](#)

EXAMPLE:

```
// The following calls
// the Windows MessageBeep() function:
#define MESSAGE_BEEP_ORDINAL 104
SElib.dynamicLink("USER.EXE", MESSAGE_BEEP_ORDINAL,
    SWORD16, PASCAL, 0);

// The following displays a simple message box
// and waits for user to press <Enter>.
#define MESSAGE_BOX_ORDINAL 1
#define MB_OK 0x0000
// Message box contains one push button: OK.
#define MB_TASKMODAL 0x2000
// Must respond to this message
SElib.dynamicLink("USER.EXE", MESSAGE_BOX_ORDINAL,
    SWORD16, PASCAL, null,
    "This is a simple message box",
    "Title of box", MB_OK | MB_TASKMODAL);

// The following accomplishes
// the same thing as above.
```

---

---

```

#define MB_OK 0x0000
// Message box contains one push button: OK.
#define MB_TASKMODAL 0x2000
// Must respond to message
SElib.dynamicLink("USER", "MESSAGEBOX", SWORD16,
    PASCAL, null,
    "This is a simple message box",
    "Title of box", MB_OK | MB_TASKMODAL);

```

---

## SElib.dynamicLink() - for Win16

---

**SYNTAX:** SElib.dynamicLink(library, procedure, returnType, convention[, [desc,] param ...])

**WHERE:** library - a string, the name of the dynamic link library, DLL, being used, the one having the procedure being called.

procedure - a string or number, the name or ordinal number of a routine in a dynamic link library to be used.

returnType - a number, which tells ScriptEase what type of value the procedure returns, so that it can be properly converted into an integer. The be one of the following:

```

UWORD8   SWORD8   UWORD16   SWORD16   UWORD24
SWORD24  UWORD32  SWORD32   FLOAT32   FLOAT64
FLOAT80  (FLOAT80 is not available in Win32)

```

convention - the calling convention to use when invoking or using the procedure being called.

```

CDECL    Push right parameter first.
          Caller pops parameters.
STDCALL  Push right parameter first.
          Caller pops parameters.
PASCAL   Push left parameter first.
          Callee pops parameters.

```

desc - a blobDescriptor that describes the following param if param is a structure. (See [blobDescriptor example](#).) A blobDescriptor is only used in front of params that are structures and is required for such params. A Blob (Binary Large Object) and a Buffer are very similar in ScriptEase. The Blob is the type that was used, in the early days of ScriptEase, to work with data in sections of memory. The Buffer is the newer type. Structure types may be created in Blobs or Buffers and blobDescriptors may be used to describe the data in either type. So, in ScriptEase, you will sometimes see blobDescriptor before a param of type Blob or a param of type buffer. In either case, the blobDescriptor is describing how data is stored in the param, even if the data is a string.

param - a variable for a section of memory that holds data in the form of a structure of elements or a buffer a string.

**RETURN:** value - the value returned by the procedure being called, else void if the procedure does not return a value.

**DESCRIPTION:** For Win16

---

---

Calls a routine in a dynamic link library, DLL. The most common use is to use various functions in the Windows API.

If a parameter is a Blob, a byte-array, or an undefined value, it is passed as a far pointer. All other numeric values are passed as 16-bit values. If 32 bits are needed, the parameter must be passed in parts, with the low word first and the high word second for CDECL calls but the high word first and low word second for PASCAL calls.

If a parameter is undefined when `SElib.dynamicLink()` is called, then it is assumed that the parameter is a far pointer to be filled in, that is, that the far address of a data element is passed to the function and that function will set the value. If any parameter is a structure, then it must be a structure that defines the binary data types in memory to represent the following variable. Before calling the DLL function, the structure will be copied to a binary buffer as described in `Blob.put()` and `Clib.fwrite()`. After calling the DLL function, the binary data is converted back into the data structure according to the rules defined in `Blob.get()` and `Clib.fread()`. Data conversion is performed according to the current `_BigEndianMode` setting.

SEE: [Blob object](#), [blobDescriptor example](#), Win32 structure definitions, [Clib.fread\(\)](#)

---

### **SElib.dynamicLink() - for OS/2**

SYNTAX: `SElib.dynamicLink(library, procedure, bitSize, convention[, [desc,] param ...])`

WHERE: `library` - a string, the name of the dynamic link library, DLL, being used, the one having the procedure being called.

`procedure` - a string or number, the name or ordinal number of a routine in a dynamic link library to be used.

`bitSize` - indicates whether this call is 16-bit or 32-bit and may be either of two defined values: BIT16 or BIT32.

`convention` - the calling convention to use when invoking or using the procedure being called.

CDECL	Push right parameter first. Caller pops parameters.
STDCALL	Push right parameter first. Caller pops parameters.
PASCAL	Push left parameter first. Callee pops parameters.

`desc` - a blobDescriptor that describes the following param if param is a structure. (See [blobDescriptor example](#).) A blobDescriptor is only used in front of params that are structures and is required for such params. A Blob (Binary Large Object) and a Buffer are very similar in ScriptEase. The Blob is the type that was used, in the early days of ScriptEase, to work with data in sections of memory. The Buffer is the newer type. Structure

---

---

types may be created in Blobs or Buffers and blobDescriptors may be used to describe the data in either type. So, in ScriptEase, you will sometimes see blobDescriptor before a param of type Blob or a param of type buffer. In either case, the blobDescriptor is describing how data is stored in the param, even if the data is a string.

param - a variable for a section of memory that holds data in the form of a structure of elements or a buffer a string.

RETURN: value - the value returned by the procedure being called, else void if the procedure does not return a value.

DESCRIPTION: For OS/2

Calls a routine in a dynamic link library, DLL.

Any parameters required by a dynamically linked function should be passed at the end of the parameters listed above, as indicated by the ellipsis at the end of the parameter list. These variables are interpreted as follows, depending on the operating system.

For 32-bit functions, all values are passed as 32-bit values. For 16-bit functions, if the parameter is a Blob, a byte-array, or an undefined value, then it is passed as a 16:16 segment:offset pointer, otherwise all numeric values are passed as 16-bit values, so if 32-bits are needed they must be passed in parts, with the low word first and the high word second.

If a parameter is undefined when `SElib.dynamicLink()` is called, then it is assumed that parameter is a 32-bit value to be filled in, that is, that the address of a 32-bit data element is passed to the function and that function will set the value. If any parameter is a structure then it must be a structure that defines the binary data types in memory to represent the following variable. Before calling the DLL function, the structure is copied to a binary buffer as described in `Blob.put()` and `Clib.fwrite()`. After calling the DLL function, the binary data is converted back into the data structure according to the rules defined in `Blob.get()` and `Clib.fread()`. Data conversion is performed according to the current `_BigEndianMode` setting.

An alternative syntax:

The OS/2 processor also allows you to call a function via a call gate with the following syntax:

```
SElib.dynamicLink(callGate, bitSize, convention,  
...)
```

Where callGate is the gate selector for a routine referenced through a call gate.

SEE: [Blob object](#), [blobDescriptor example](#), [Clib.fread\(\)](#)

---

---

# String Object

The String object is a data type and is a hybrid that shares characteristics of primitive data types and of composite data types. The String is presented in this section under two main headings in which the first describes its characteristics as a primitive data type and the second describes its characteristics as an object.

## String as data type

A string is an ordered series of characters. The most common use for strings is to represent text. To indicate that text is a string, it is enclosed in quotation marks. For example, the first statement below puts the string "hello" into the variable `hello`. The second sets the variable `word` to have the same value as a previous variable `hello`:

```
var hello = "hello";
var word = hello;
```

## Escape sequences for characters

Some characters, such as a quotation mark, have special meaning to the interpreter and must be indicated with special character combinations when used in strings. This allows the interpreter to distinguish between a quotation mark that is part of a string and a quotation mark that indicates the end of the string. The table below lists the characters indicated by escape sequences:

<code>\a</code>	Audible bell	
<code>\b</code>	Backspace	
<code>\f</code>	Formfeed	
<code>\n</code>	Newline	<b>Error! Reference source not found.</b>
<code>\r</code>	Carriage return	
<code>\t</code>	Horizontal Tab	
<code>\v</code>	Vertical tab	
<code>\'</code>	Single quote	
<code>\"</code>	Double quote	
<code>\\</code>	Backslash character	
<code>\0</code>	Null character	(e.g., <code>"\0"</code> is the null character)
<code>\###</code>	Octal number (0-7)	(e.g., <code>"033"</code> is the escape character)
<code>\x##</code>	Hex number (0-F)	(e.g., <code>"x1B"</code> is the escape character)
<code>\u####</code>	Unicode number (0-F)	(e.g., <code>"u001B"</code> is escape character)

Note that these escape sequences cannot be used within strings enclosed by back quotes, which are explained below.

## Single quote

You can declare a string with single quotes instead of double quotes. There is no difference between the two in JavaScript, except that double quote strings are used less commonly by many scripters.

## Back quote

ScriptEase provides the back quote "`", also known as the back-tick or grave accent, as an alternative quote character to indicate that escape sequences are not

to be translated. Any special characters represented with a backslash followed by a letter, such as "\n", cannot be used in back tick strings.

For example, the following lines show different ways to describe a single file name:

```
"c:\\autoexec.bat" // traditional C method
'c:\\autoexec.bat' // traditional C method
`c:\\autoexec.bat` // alternative ScriptEase method
```

Back quote strings are not supported in most versions of JavaScript. So if you are planning to port your script to some other JavaScript interpreter, you should not use them.

## String as object

Strictly speaking, the String object is not truly an object. It is a hybrid of a primitive data type and of an object. As an example of its hybrid nature, when strings are assigned using the assignment operator, the equal sign, the assignment is by value, that is, a copy of a string is actually transferred to a variable. Further, when strings are passed as arguments to the parameters of functions, they are passed by value. Objects, on the other hand, are assigned to variables and passed to parameters by reference, that is, a variable or parameter points to or references the original object.

Strings have both properties and methods which are listed in this section. These properties and methods are discussed as if strings were pure objects. Strings have instance properties and methods and are shown with a period, ".", at their beginnings. A specific instance of a variable should be put in front of a period to use a property or call a method. The exception to this usage is a static method which actually uses the identifier String, instead of a variable created as an instance of String. The following code fragment shows how to access the .length property, as an example for calling a String property or method:

```
var TestStr = "123";
var TestLen = TestStr.length;
```

String properties

## String object instance properties

### String length

---

SYNTAX:	string.length
DESCRIPTION:	The length of a string, that is, the number of characters in a string. JavaScript strings may contain the "\\0" character.
SEE:	<a href="#">String lastIndexOf()</a>
EXAMPLE:	<pre>var s = "a string"; var n = s.length;</pre>

---

## String object instance methods

### String()

---

SYNTAX:	new String([value])
---------	---------------------

---

---

WHERE:	value - value to be converted to a string as this string object.
RETURN:	This method returns a new string object whose value is the supplied value.
DESCRIPTION:	If <code>value</code> is not supplied, then the empty string "" is used instead. Otherwise, the value <code>ToString(value)</code> is used. Note that if this function is called directly, without the new operator, then the same construction is done, but the returned variable is converted to a string, rather than being returned as an object.
SEE:	<code>RegExp()</code>
EXAMPLE:	<pre>var s = new String(123);</pre>

---

### **String charAt()**

---

SYNTAX:	<code>string.charAt(position)</code>
WHERE:	position - offset within a string.
RETURN:	string - character at position
DESCRIPTION:	This method gets the character at the specified position. If no character exists at location <code>position</code> , or if <code>position</code> is less than 0, then <code>NaN</code> is returned.
SEE:	<a href="#">String charCodeAt()</a>
EXAMPLE:	<pre>// To get the first character in a string, // use as follows:  var string = "a string"; string.charAt(0);  // To get the last character in a string, use: string.charAt(string.length - 1);</pre>

---

### **String charCodeAt()**

---

SYNTAX:	<code>string.charCodeAt(index)</code>
WHERE:	position - index of the character the encoding of which is to be returned.
RETURN:	number - representing the unicode value of the character at position <code>index</code> of a string. Returns <code>NaN</code> if there is no character at the position.
SEE:	<a href="#">String charAt()</a> , <a href="#">String.fromCharCode()</a>
DESCRIPTION:	This method gets the <code>n</code> th character code from a string.

---

### **String concat()**

---

SYNTAX:	<code>string.concat([string1, ...])</code>
WHERE:	<code>stringN</code> - A list of strings to append to the end of the current object.
RETURN:	This method returns a string value (not a string object) consisting of the current object and any subsequent arguments appended to

---

---

it.

**DESCRIPTION:** This method creates a new string whose contents are equal to the current object. Each argument is then converted to a string using [global.ToString\(\)](#) and appended to the newly created string. This value is then returned. Note that the original object remains unaltered. The '+' operator performs the same function.

**SEE:** [Array concat\(\)](#)

**EXAMPLE:**

```
// The following line:

var proverb = "A rolling stone " + "gathers no moss."

// creates the variable proverb and
// assigns it the string
// "A rolling stone gathers no moss."
// If you try to concatenate a string with a number,
// the number is converted to a string.

var newstring = 4 + "get it";

// This bit of code creates newstring as a string
// variable and assigns it the string
// "4get it".

// The use of the + operator is the standard way of
// creating long strings in JavaScript.
// In ScriptEase, the + operator is optional.
// For example, the following:

var badJoke = "I was in front of an Italian "
    "restaurant waiting to get in when this guy "
    "came up and asked me, \"Why did the "
    "Italians lose the war?\" I told him I had "
    "no idea. \"Because they ordered ziti"
    "instead of shells,\" he replied."

// creates a long string containing
// the entire bad joke.
```

---

## **String indexOf()**

---

**SYNTAX:** `string.indexOf(substring[, offset])`

**WHERE:** `substring` - substring to search for within string.

`offset` - optional integer argument which specifies the position within string at which the search is to start. Default is 0.

**RETURN:** number - index of the first appearance of a substring in a string, else -1, if substring not found.

**DESCRIPTION:** `String indexOf()` searches the string for the string specified in `substring`. The search begins at `offset` if `offset` is specified; otherwise the search begins at the beginning of the string. If `substring` is found, `String indexOf()` returns the position of its first occurrence. Character positions within the string are numbered in increments of one beginning with zero.

**SEE:** [String charAt\(\)](#), [String lastIndexOf\(\)](#), [String substring\(\)](#)

---

---

EXAMPLE: `var string = "what a string";  
string.indexOf("a")`

`// returns the position, which is 2 in this example,  
// of the first "a" appearing in the string.  
// The method indexOf() may take an optional second  
// parameter which is an integer indicating the index  
// into a string where the method starts searching  
// the string. For example:`

`var magicWord = "abracadabra";  
var secondA = magicWord.indexOf("a", 1);`

`// returns 3, index of the first "a" to be found in  
// the string when starting from the second letter of  
// the string.  
// Since the index of the first character is 0, the  
// index of second character is 1.`

---

### String lastIndexOf()

---

SYNTAX: `string.lastIndexOf(substring[, offset])`

WHERE: `substring` - The substring that is to be searched for within string

`offset` - An optional integer argument which specifies the position within string at which the search is to start. Default is 0.

RETURN: number - index of the last appearance of a substring in a string, else -1, if `substring` not found.

SEE: [String indexOf\(\)](#)

DESCRIPTION: This method is similar to [String indexOf\(\)](#), except that it finds the last occurrence of a character in a string instead of the first.

---

### String localeCompare()

---

SYNTAX: `string.localeCompare(compareStr)`

WHERE: `compareStr` - a string with which to compare an instance string.

RETURN: number - indicating the relationship of two strings.

- `< 0` if string is less than `compareStr`
- `= 0` if string is the same as `compareStr`
- `> 0` if string is greater than `compareStr`

DESCRIPTION: This method returns a number that represents the result of a locale-sensitive string comparison of this object with that object. The result is intended to order strings in the sort order specified by the system default locale, and will be negative, zero, or positive, depending on whether string comes before `compareStr` in the sort order, the strings are equal, or string comes after `compareStr`.

SEE: [Clib.strcmpi\(\)](#), [Clib.stricmp\(\)](#)

EXAMPLE:

---

### String match()

---

SYNTAX:	<code>string.match(pattern)</code>
WHERE:	<p><code>pattern</code> - a regular expression pattern to find or match in <code>string</code>. May be a regular expression or a value, such as, a string, that may be converted into a regular expression using the <code>RegExp()</code> constructor. For example, both of the following are equivalent:</p> <pre>var rtn = "one two three".match(/two/); var rtn = "one two three".match("two");</pre>
RETURN:	<p>array - an array with various elements and properties set depending on the attributes of a regular expression. Returns <code>null</code> if no match is found.</p>
DESCRIPTION:	<p>This method behaves differently depending on whether <code>pattern</code> has the "g" attribute, that is, on whether the match is global.</p> <p>If the match is not global, <code>string</code> is searched for the first match to <code>pattern</code>. A <code>null</code> is returned if no match is found. If a match is found, the return is an array with information about the match. Element 0 has the text matched. Elements 1 and following have the text matched by sub patterns in parentheses. The element numbers correspond to group numbers in regular expression reference characters and regular expression replacement characters. The array has two extra properties: <code>index</code> and <code>input</code>. The property <code>index</code> has the position of the first character of the text matched, and <code>input</code> has the target string.</p> <p>If the match is global, <code>string</code> is searched for all matches to <code>pattern</code>. A <code>null</code> is returned if no match is found. If one or more matches are found, the return is an array in which each element has the text matched for each find. There are no <code>index</code> and <code>input</code> properties. The <code>length</code> property of the array indicates how many matches there were in the target string.</p> <p>If any matches are made, appropriate <code>RegExp</code> object static properties, such as <code>RegExp.leftContext</code>, <code>RegExp.rightContext</code>, <code>RegExp.\$n</code>, and so forth are set, providing more information about the matches.</p>
SEE:	<p><code>RegExp exec()</code>, <a href="#">String replace()</a>, <a href="#">String search()</a>, Regular expression replacement characters, <code>RegExp</code> object static properties</p>
EXAMPLE:	<pre>// not global var pat = /(t(.)o)/; var str = "one two three tio one"; // rtn == "two" // rtn[0] == "two" // rtn[1] == "o" // rtn[2] == "w" // rtn.index == 4 // rtn.input == "one two three two one" rtn = str.match(pat);  // global var pat = /(t(.)o)/g; var str = "one two three tio one"; // rtn[0] == "two"</pre>

---

---

```
// rtn[1] == "tio"  
// rtn.length == 2  
rtn = str.match(pat);
```

---

## String replace()

---

SYNTAX: `string.replace(pattern, replexp)`

WHERE: `pattern` - a regular expression pattern to find or match in string.

`replexp` - a replacement expression which may be a string, a string with regular expression elements, or a function.

RETURN: string - the original string with replacements in it made according to `pattern` and `replexp`.

DESCRIPTION: This string is searched using the regular expression pattern defined by `pattern`. If a match is found, it is replaced by the substring defined by `replexp`. The parameter `replexp` may be a:

- a simple string
- a string with special regular expression replacement elements in it
- a function that returns a value that may be converted into a string

If any replacements are done, appropriate RegExp object static properties, such as `RegExp.leftContext`, `RegExp.rightContext`, `RegExp.$n`, and so forth are set, providing more information about the replacements.

The special characters that may be in a replacement expression are (see regular expression replacement characters):

- `$1`, `$2` ... `$9`  
The text that is matched by regular expression patterns inside of parentheses. For example, `$1` will put the text matched in the first parenthesized group in a regular expression pattern. See (...) under regular expression reference characters.
  - `$+`  
The text that is matched by the last regular expression pattern inside of the last parentheses, that is, the last group.
  - `$&`  
The text that is matched by a regular expression pattern.
  - `$``  
The text to the left of the text matched by a regular expression pattern.
  - `$'`  
The text to the right of the text matched by a regular expression pattern.
  - `\$`  
The dollar sign character.
-

---

SEE: [String match\(\)](#), [String search\(\)](#), Regular expression replacement characters, RegExp object static properties

EXAMPLE:

```
var rtn;
var str = "one two three two one";
var pat = /(two)/g;

// rtn == "one zzz three zzz one"
rtn = str.replace(pat, "zzz");
// rtn == "one twozzz three twozzz one";
rtn = str.replace(pat, "$1zzz");
// rtn == "one 5 three 5 one"
rtn = str.replace(pat, five());
// rtn == "one twotwo three twotwo one";
rtn = str.replace(pat, "$&$&");

function five()
{
    return 5;
}
```

---

## String search()

---

SYNTAX: `string.search(pattern)`

WHERE: `pattern` - a regular expression pattern to find or match in string.

RETURN: `number` - the starting position of the first matched portion or substring of the target string. Returns -1 if there is no match.

DESCRIPTION: This method returns a number indicating the offset within the string where the pattern matched or -1 if there was no match. The return is the same character position as returned by the simple search using [String indexOf\(\)](#). Both `search()` and `indexOf()` return the same character position of a match or find. The difference is that `indexOf()` is simple and `search()` is powerful.

The `search()` method ignores a "g" attribute if it is part of the regular expression pattern to be matched or found. That is, `search()` cannot be used for global searches in a string.

After a search is done, the appropriate RegExp object static properties are set.

SEE: [String match\(\)](#), [String replace\(\)](#), [RegExp exec\(\)](#), Regular expression syntax, RegExp Object, RegExp object static properties

EXAMPLE:

```
var str = "one two three four five";
var pat = /th/;
str.search(pat); // == 8, start of th in three
str.search(/t/); // == 4, start of t in two
str.search(/Four/i); // == 14, start of four
```

---

## String slice()

---

SYNTAX: `string.slice(start[, end])`

WHERE: `start` - index from which to start.

`end` - index at which to end.

---

---

RETURN:	string - a substring (not a String object) consisting of the characters.
SEE:	<a href="#">String substring()</a>
DESCRIPTION:	This method is very similar to <a href="#">String substring()</a> , in that it returns a substring from one index to another. The only difference is that if either <code>start</code> or <code>end</code> is negative, then it is treated as <code>length + start</code> or <code>length + end</code> . If either exceeds the bounds of the string, then either 0 or the length of the string is used instead.

---

### **String split()**

---

SYNTAX:	<code>string.split([delimiterString])</code>
WHERE:	<code>delimiterString</code> - character, string or regular expression where the string is split. If <code>substring</code> is not specified, an array will be returned with the name of the <code>string</code> specified. Essentially this will mean that the string is split character by character.
RETURN:	object - if no delimiters are specified, returns an array with one element which is the original string.
DESCRIPTION:	This method splits a string into an array of strings based on the delimiters in the parameter <code>delimiterString</code> . The parameter <code>delimiterString</code> is optional and if supplied, determines where the string is split.
SEE:	<a href="#">Array join()</a>
EXAMPLE:	<pre>/* For example, to create an array of all of the words in a sentence, use code similar to the following fragment: */  var sentence = "I am not a crook"; var wordArray = sentence.split(' ');</pre>

---

### **String substr()**

---

SYNTAX:	<code>string.substr(start, length)</code>
WHERE:	<code>start</code> - integer specifying the position within the string to begin the desired substring. If <code>start</code> is positive, the position is relative to the beginning of the string. If <code>start</code> is negative, the position is relative to the end of the string.  <code>length</code> - the length, in characters, of the substring to extract.
RETURN:	string - a substring starting at position <code>start</code> and including the next number of characters specified by <code>length</code> .
DESCRIPTION:	This method gets a section of a string. The <code>start</code> parameter is the first character in the new string. The <code>length</code> parameter determines how many characters to include in the new substring.  This method, <code>substr()</code> differs from <a href="#">String substring()</a> in two basic ways. One, in <code>substring()</code> the start position cannot be

---

---

negative, that is, it must be 0 or greater. Two, the second parameter in `substring()` indicates a position to go to, not the length of the new substring.

SEE: [String substring\(\)](#)

EXAMPLE: 

```
var str = ("0123456789");
str.substr(0, 5)    // == "01234"
str.substr(2, 5)    // == "23456"
str.substr(-4, 2)   // == "56"
```

---

## String substring()

---

SYNTAX: `string.substring(start, end)`

WHERE: `start` - integer specifying the position within the string to begin the desired substring.

`end` - integer specifying the position within the string to end the desired substring.

RETURN: `string` - a substring starting at position `start` and going to but not including position `end`.

DESCRIPTION: This method retrieves a section of a string. The `start` parameter is the index or position of the first character to include. The `end` parameter marks the end of the string. The end position is the index or position after the last character to be included. The length of the substring retrieved is defined by `end` minus `start`. Another way to think about the `start` and `end` positions is that `end` equals `start` plus the length of the substring desired.

SEE: [String charAt\(\)](#), [String indexOf\(\)](#), [String lastIndexOf\(\)](#), [String slice\(\)](#), [String substr\(\)](#)

EXAMPLE: 

```
// For example, to get the first nine characters
// in string, use a Start position
// of 0 and add 9 to it, that is,
// "0 + 9", to get the End position
// which is 9. The following fragment illustrates.

var str = "0123456789";
str.substring(0, 5)    // == "01234"
str.substring(2, 5)    // == "234"
str.substring(0, 10)   // == "0123456789"
```

---

## String toLocaleLowerCase()

---

SYNTAX: `string.toLocaleLowerCase()`

RETURN: `string` - a copy of a string with each character converted to lower case.

DESCRIPTION: This method behaves exactly the same as [String toLowerCase\(\)](#). It is designed to convert the string to lower case in a locale sensitive manner, though this functionality is currently unavailable. Once it is implemented, this function may behave differently for some locales (such as Turkish), though for the majority it will be identical to `toLowerCase()`.

---

---

SEE: [String toLowerCase\(\)](#), [String toLocaleUpperCase\(\)](#)

---

### **String toLocaleUpperCase()**

---

SYNTAX: `string.toLocaleUpperCase()`

RETURN: string - a copy of a string with each character converted to upper case.

DESCRIPTION: This method behaves exactly the same as [String toUpperCase\(\)](#). It is designed to convert the string to upper case in a locale sensitive manner, though this functionality is currently unavailable. Once it is implemented, this function may behave differently for some locales (such as Turkish), though for the majority it will be identical to `toUpperCase()`.

SEE: [String toUpperCase\(\)](#), [String toLocaleLowerCase\(\)](#)

---

### **String toLowerCase()**

---

SYNTAX: `string.toLowerCase()`

RETURN: string - copy of a string with all of the letters changed to lower case.

DESCRIPTION: This method changes the case of a string.

SEE: [String toUpperCase\(\)](#), [String toLocaleLowerCase\(\)](#)

EXAMPLE: 

```
var string = new String("Hello, World!");
string.toLowerCase()

// This will return the string "hello, world!".
```

---

### **String toUpperCase()**

---

SYNTAX: `string.toUpperCase()`

RETURN: string - a copy of a string with all of the letters changed to upper case.

DESCRIPTION: This method changes the case of a string.

SEE: [String toLowerCase\(\)](#), [String toLocaleUpperCase\(\)](#)

EXAMPLE: 

```
var string = new String("Hello, World!");
string.toUpperCase()

// This will return the string
// "HELLO, WORLD!".
```

---

## **String object static methods**

### **String.fromCharCode()**

---

SYNTAX: `String.fromCharCode(chrCode[, ...])`

WHERE: `chrCode` - character code, or list of codes, to be converted.

RETURN: string - string created from the character codes that are passed to it as parameters.

DESCRIPTION: The identifier `String` is used with this static method, instead of a variable name as with instance methods. The arguments passed

---

---

to this method are assumed to be unicode characters.

SEE: [String\(\)](#), [String.charCodeAt\(\)](#)

EXAMPLE: 

```
// The following code:  
var string = String.fromCharCode(0x0041,0x0042)  
// will set the variable string to be "AB".
```

---

---

# Unix Object

platform: Unix OS, all versions of SE

## Unix object static methods

---

### Unix.fork()

SYNTAX: `Unix.fork()`

RETURN: number - 0 or a child process id. 0 is returned to the child process, the id of the child process is returned to the parent.

DESCRIPTION: A call to this function creates two duplicate processes. The processes are exact copies of the currently running process, so both pick up execution from the next statement. Because these processes are duplicates, they share identical all resources the original one had at the time of `fork()`ing, but not any allocated later. For instance, any open file handles or sockets are shared. If both processes write to them, the output will be intermixed since each write from either process advances the file pointer for both. [Unix.wait\(\)](#) allows you to wait for completion of a Child. Using `Unix.wait()` or [Unix.waitpid\(\)](#) is important to prevent annoying zombie processes from building up.

SEE: [Unix.kill\(\)](#), [Unix.wait\(\)](#), [Unix.waitpid\(\)](#)

EXAMPLE: `// Here is a simple example:`

```
function main()
{
    var id = Unix.fork();

    if( id==0 )
    {
        Clib.printf("Child here!\n");
        Clib.exit(0);
    }
    else
    {
        Clib.printf("started child process %d\n", id);
    }
}
```

---

### Unix.kill()

SYNTAX: `Unix.kill(pid, signal)`

WHERE: `pid` - process to kill.

`signal` - the signal to send the process.

RETURN: number - 0 for success, -1 for error.

DESCRIPTION: This is simply a direct wrapper for the Unix kill command. To get documentation on it for your particular Unix system, just type 'man 2 kill'

SEE: [Unix.fork\(\)](#)

EXAMPLE: `// Typically you would use this to kill a child,`

---

---

```

// for instance:

if( var id = Unix.fork() )
{
    while(1)
        Clib.printf("I am an annoying child.\n");
}
else
{
    // child would be too annoying, so kill it
    Unix.kill(id,9); //9 is SIGKILL
    Unix.wait(var status); //wait until child is dead
    Clib.printf(
        "I hope DSS doesn't here about this...\n");
}

```

---

### Unix.setgid()

---

SYNTAX: `Unix.setgid(id)`  
WHERE: `id` - group id to set.  
RETURN: number - 0 for success, -1 for error.  
DESCRIPTION: Changes the group ID to the given ID, if allowed.  
SEE: [Unix.setuid\(\)](#)

---

### Unix.setsid()

---

SYNTAX: `Unix.setsid()`  
RETURN: number - 0 for success, -1 for error.  
DESCRIPTION: Creates a new session with no terminal, most useful for having commands that, when run, immediately have the terminal prompt reappear, but continue to run in the background.  
SEE: [Unix.fork\(\)](#)  
EXAMPLE: `// A typical daemon program has a line like this:`

```

#ifdef _UNIX_
    Unix.setsid(); if( Unix.fork() ) Clib.exit(0);
#endif

// which detaches the program from the terminal and
// continues. Notice, this for line means that
// only the child is running. Because the parent
// has exited and the child does not have the
// original file handles, the shell thinks
// the program is done and goes back to the prompt.

```

---

### Unix.setuid()

---

SYNTAX: `Unix.setuid(id)`  
WHERE: `id` - user id to set.  
RETURN: number - 0 for success, -1 for error.  
DESCRIPTION: Changes the user ID to the given ID, if allowed.  
SEE: [Unix.setgid\(\)](#)

---

## Unix.wait()

---

**SYNTAX:** `Unix.wait(status)`  
**WHERE:** `status` - status of the process.

**RETURN:** number - process id of the exiting child, else -1 for error.

**DESCRIPTION:** A call to `Unix.wait()` will suspend execution until a child process terminates, then return the id of the particular child that exited. The status parameter is filled in with the status code for the process (this is the raw data exactly as returned by the underlying C `wait()` call provided for Unix gurus who find this information useful.) Any resources used by the Child are cleaned up.

**SEE:** [Unix.kill\(\)](#), [Unix.waitpid\(\)](#)

**EXAMPLE:** `// Here is a simple example:`

```
function main()
{
    var id = Unix.fork();

    if( id==0 )
    {
        Clib.printf("Child here!\n");
        Clib.exit(0);
    }
    else
    {
        Clib.printf("started child process %d\n", id);
        Clib.assert( Unix.wait(var dontcare)==id );
        Clib.printf("child process is dead meat.\n");
    }
}
```

---

## Unix.waitpid()

---

**SYNTAX:** `Unix.waitpid(pid, status, flags)`  
**WHERE:** `pid` - child process interested in or -1 for any.  
`status` - status of the process.  
`flags` - WNOHANG or 0.

**RETURN:** number - process id of the exiting child, else -1 for error.

**DESCRIPTION:** Very similar to [Unix.wait\(\)](#), except you can specify which child process you care about as well as some flags. The only flag currently given a name is WNOHANG, which means that if no child is ready to exit, the call returns immediately. Unix gurus who need the full functionality can put the other possible flag values here.

**SEE:** [Unix.kill\(\)](#), [Unix.waitpid\(\)](#)

**EXAMPLE:** `// This function is most useful in the main loop  
// of a server daemon  
// (see inn.jse, unix/daemon.jse samples.)  
// By calling it each time through the loop such as:`

---

---

```
Unix.waitpid(-1,var status, WNOHANG);  
  
// Child processes will get cleaned up and  
// zombie processes will not stick around  
// wasting resources.
```

---

# Link Libraries

Link libraries are dynamic link library files (.dll files) developed specifically to work with ScriptEase. ScriptEase can use any DLL, but the calling conventions needed to call routines in a DLL are necessarily more cumbersome than calling internal routines. ScriptEase extends the power and ease of using its link libraries by tying them to the internal data structures of ScriptEase. In this way, the data and routines in a link library are available with the same calling conventions of internal routines. Consider the two following code fragment:

```
// Using dynamicLink
var v1 = SElib.dynamicLink("YourDll.dll", "FunctionOne", STDCALL,
args ...);
var v2 = SElib.dynamicLink("YourDll.dll", "FunctionTwo", STDCALL,
args ...);

// Using a link library
#link <SElink.dll>
var v1 = FunctionOne(args ...);
var v2 = FunctionTwo(args ...);
```

As you can see in the first three lines, every time you want to call a routine from a general DLL, you must use the more cumbersome `SElib.dynamicLink()` method and its cumbersome calling conventions. Cumbersome calling conventions exist in any language that allows general DLL files to be called. But, notice the difference after a ScriptEase link DLL is linked into a script, as illustrated by the line, `#link <SElink.dll>`. The routines and data in the DLL are accessible in the same way as internal routines such as `Screen.writeln()`.

Script libraries, scripts that end with `.jsh`, can be used to define objects, methods, properties, functions, and data. The advantage of script libraries is that you may develop them quickly and alter them at any time. An advantage of link libraries is that they execute faster since they compiled executables.

The following sections explain various link libraries. To use these link libraries, they must be included in a script with the `#link <>` preprocessor directive. Most link libraries have a corresponding script library, `.jsh` file, that simplifies their use even more.

**See:**

- [Com Object Link Library](#)
- [DSP Link Library](#)
- [GD Link Library](#)
- [MD5 Checksum Link Library](#)
- [SEDBC Link Library](#)
- [Socket Link Library](#)
- [UUCode Link Library](#)

---

# COM Object Link Library

The ScriptEase COM object consists of three functions: [COMCreateObject\(\)](#) to create a COM object link, [COMGetObject\(\)](#) to create a COM object link, and [COMCreateObject\(\)](#) to force the COM object to be released early.

## COM object

```
title: COM object link library
platform: WINDOWS; All versions except WMLScriptEase
source: #link <comobj>
```

The Component Object Model, COM, allows communication among the software of various applications, at least applications that support COM. The COM object library provides the ability to use COM objects from within scripts. COM is underneath a number of technologies, such as, ActiveX Automation, ActiveX controls, and ActiveX documents.

In general, the technique that allows one application to use objects in another is known as *Automation*, which some people may remember by an older phrase, *OLE Automation*. An application may be an *Automation server* or an *Automation client* (also known as an *Automation controller*). The ScriptEase function [COMCreateObject\(\)](#) allows a script to be an Automation client but not an Automation server.

A full description of COM objects is beyond the scope of this reference manual. Since each Automation server exposes its own objects with unique names, a scripter must have the documentation for the objects of the applications to be used. ScriptEase only provides the ability to connect to and use COM objects.

---

### COMCreateObject()

SYNTAX:	COMCreateObject(COMObject)
WHERE:	COMObject - the name of a COM object. Refer to the documentation for particular applications to get the names that may be used.
RETURN:	object - an instance of the specified COM object.
DESCRIPTION:	Create an instance of a COM object to be used in a script. When this function is used, an Automation server is started, and an instance of a COM object is established. COMCreateObject() does not get or connect to an existing instance of a COM object in another application. Rather, it starts a new instance of an object in another application.
SEE:	#link <comobj>, <a href="#">COM object</a> , <a href="#">COMGetObject</a> , <a href="#">COMReleaseObject</a>
EXAMPLE:	<pre>/*   This example script was tested with Word 2000   but should work with Word 97. Word does not   need to be running, just installed. */  #link "comobj"  var text =</pre>

---

---

```

"Nombas, Inc.\n"
"\n"
"To All ScriptEase users:\n"
"\n"
"The Component Object Model is very powerful "
"and might be worth the time to learn how "
"to use. By using Automation, "
"you may automate and control many applications "
"from ScriptEase scripts, as is being "
"illustrated by this simple example "
"of automating Word.\n";

/*
   These next few lines connect to a new
   instance of a COM object in Word. Both of the
   succeeding illustrations rely on these
   initial lines but show how to do the same
   thing using different approaches. Either
   approach is acceptable.
*/
var wd;
wd = COMCreateObject("Word.Application");
wd.visible = true;

/*
   This first illustration of putting text into
   a Word document uses the properties of
   the Word.Application object and does not
   define any new ScriptEase variables.

   Since we start a new instance of word, when
   we add a document, it is document 1.
*/
wd.documents.add;
wd.documents(1).content = text;

/*
   This second illustration defines a new
   variable to point to a property of the
   Word.Application object and uses that
   variable.

   When we add another document, we define the
   variable doc to point to it. Thus, we do not
   have to worry about the document number.
*/
var doc;
doc = wd.documents.add;
doc.content = text;

```

---

### **COMGetObject()**

---

SYNTAX: COMGetObject(file, COMObject)

WHERE: file - the file hosting the COM object.

COMObject - the name of a COM object. Refer to the documentation for particular applications to get the names that may be used.

RETURN: object - an instance of the specified COM object.

DESCRIPTION: Create an instance of a COM object to be used in a script.

---

---

Unlike `COMCreateObject()`, `COMGetObject` does get or connect to an existing instance of a COM object in another application.

SEE: [#link <comobj>](#), [COM object](#), [COMCreateObject](#), [COMReleaseObject](#)

---

## **COMReleaseObject()**

---

SYNTAX: `COMReleaseObject(COMObject)`

WHERE: `COMObject` - An object returned with `COMCreateObject()` or `COMGetObject()`.

RETURN: none

DESCRIPTION: Release all internal locks on a COM object created with `COMCreateObject()` or `COMGetObject()`.

In most cases a lock is held on a `COMObject` until the script is no longer using the object and the internal script-engine garbage collector has run and freed the object. Sometimes you will want the COM object to be released earlier, such as if the COM object can only work with a limited number of clients--in this case calling `COMReleaseObject` will force all locks on the COM object to be released. After `COMReleaseObject` and calls using the `COMObject` will throw an exception.

SEE: [#link <comobj>](#), [COM object](#), [COMCreateObject](#), [COMGetObject](#)

EXAMPLE:

```
/*
   This is similar to the example shown above
   for COMCreateObject. In this case the
   object will be released..
*/

#link "comobj"

var wd;
wd = COMCreateObject("Word.Application");
wd.visible = true;

COMReleaseObject(wd);

try {
    wd.visible = false; // this will fail because
                       // the object is released
}
catch(e)
{
    // this will be caught because the wd object
    // was used after it was released
}
```

---

---

# DSP Link Library

Distributed Scripting Protocol is implemented by the ScriptEase DSP link library as the DSP object.

## DSP Object

```
platform: All platforms except Dos; All versions of SE
source: #link <sedsp>
```

The DSP object provides a framework for implementing distributed scripting across a variety of computers and networks.

## Creating a DSP object

The Distributed Scripting Protocol provides no internal method for managing a connection or transporting packets. It is simply a framework, with the physical transport method being supplied by the user. As such, it is impossible to simply create a DSP object, because it is incapable of doing anything by itself. The user must supply a set of functions to manage the connection with the server. To create a DSP object, you call `new DSP(myOpenFunction, myParameters)`. The function that you supply must open the connection and return a reference to it. It is possible in some instances that you do not need to open anything special, and so you can ignore this parameter. Here is an example of an open function for a DSP connection, using internet sockets:

```
function idspOpen( host, port )
{
    return new Socket( host, port );
}
```

We will see this function passed to the DSP constructor in a moment. First, to accomplish sending/receiving packets, the user needs to define two functions, `dspSend` and `dspReceive`. These functions must be inherited through the prototype chain, because otherwise when DSP objects are copied implicitly through reference construction (see below), the functions will not get passed. Because we want to keep the DSP functions (such as `dspService`), we need to preserve the original DSP prototype, and a constructor looks like the following:

```
function iDSP( host, port )
{
    var ret = new DSP( idspOpen, host, port );
    // Now we override the ._prototype to insert our functions
    if( ret != null )
        ret._prototype = iDSP.prototype;
    return ret;
}
// Here we set up the iDSP.prototype to keep the DSP functions
// in the chain
iDSP.prototype._prototype = DSP.prototype;
```

Once this constructor is called, we have a valid DSP object, assuming we add the transport functions. To do this, we must add `dspSend` and `dspReceive` to the prototype. The actual syntax of these functions is similar to `Clib.fread()` and `Clib.fwrite()`, and a description can be found in the function reference. For our `iDSP` example, they would look something like this:

```

function iDSP.prototype.dspSend( conn, buffer, timeout )
{ // Ignore timeout
  return conn.write(buffer);
}
function iDSP.prototype.dspReceive( conn, &buffer, length,
timeout)
{
  return conn.read( buffer, length );
}

```

Note that both these functions ignore the timeout parameter and do not correctly handle errors. A full-featured version of these functions can be found in the file *idsp.jsh*. The final function that we must provide is the `dspCloseConnection` function, which is responsible for closing the connection. This function looks like the following:

```

function iDSP.prototype.dspCloseConnection( conn )
{
  conn.close();
}

```

Once all of these transport functions have been defined, new `iDSP` objects can be instantiated with a call to `new iDSP` and used as any other DSP object. Because the transport level of DSP is separate from the core library, DSP can be adapted to communicate between any servers in any way. In addition, communication can be done during the call to the open function. This allows for password authentication or any other information to be shared.

## Using a DSP object

Once a DSP object is created using the method described above, every DSP object behaves in exactly the same way. Once the functions are set up, the transport layer of the protocol is hidden.

The basic idea is that all DSP objects are in fact references to objects on the remote side, and they will remain so except under certain circumstances (described below). When a connection is first established, it is a reference to the global object. Members of the remote global object can be accessed as members of the connection. But they remain references, so `var print = connection.Clib.printf` will not actually make a remote call to the server. At the appropriate time, `print` will be resolved into `Clib.printf()` and sent to the server in the appropriate manner. The circumstances which can trigger a de-referencing and remote call are:

**Calling functions** - When a DSP reference is called as a function, it gets resolved into the appropriate path and the function is called on the remote server. All parameters are converted to source with `ToSource()` and passed to the server, and set back afterwards (in case any were passed by reference). The client waits for the return value from the server and returns that as the result of the function call. This makes calling functions transparent to the client, so `connection.Screen.writeln("hi")` will actually call `Screen.writeln` on the server and print out "hi".

**Setting a value** - When a value is put to a DSP reference, such as `connection.globalCount = 5`, a remote call to the server is generated, and

the remote value is updated. The above case acts just as if `globalCount = 5` was executed on the server.

**Implicitly** - When a DSP reference is converted to a primitive, then it gets de-referenced. This implicit conversion happens mostly in operator expressions, in which both values are converted to primitives first. So `var myCount = connection.globalCount + 1` will get the value of `globalCount` from the server and add one to it. This can also be accomplished explicitly with `ToPrimitive()`, but the method below is more straightforward and understandable. The explicit use of `ToPrimitive()` on DSP references is discouraged.

**Explicitly** - Any DSP reference can be explicitly de-referenced with a call to `.dspGetValue`. Once an object has been de-referenced this way, any subsequent accesses will not cause a remote call, and changes will only affect the local copy. Note that calling a function in this way will result in the function being called on the local client, not the server.

## DSP object instance methods

### DSP()

---

SYNTAX:	<code>new DSP( [openFunction[, param1[, ...]])</code>
WHERE:	<code>openFunction</code> - The function to call to initialize the connection.  <code>paramN</code> - Additional parameters to pass to the open function
RETURN:	object - A new DSP object, or <code>null</code> on error. This is the object that will be passed as the first parameter to all for most of the DSP methods ( <code>dspReceive</code> , <code>dspSend</code> ). Those methods should use the first passed parameter, and not the "this" variable, for any connection-specific properties or methods--because the dsp object is acting as a proxy to another system to use the "this" variable would instead be acting on the remote system.
DESCRIPTION:	This function creates a new DSP object, or returns <code>null</code> on error. Note that calling this function itself accomplishes very little unless you build up an appropriate DSP object by adding <code>open</code> , <code>close</code> , and <code>transport</code> functions. A new DSP object can be created with just <code>new DSP()</code> , but it will be unusable without transport functions. See the introduction, under <a href="#">creating a DSP object</a> , for more information about setting up a proper DSP object. The first optional parameter is the open function to use. Once the object has been created, this function is called with any additional parameters passed to <code>DSP()</code> . The result of this call is set the <code>dspConnection</code> member of the newly created object, and is only used to pass as the first parameters to the <code>dspSend</code> , <code>dspReceive</code> , and <code>dspCloseConnection</code> methods. If <code>openFunction</code> is supplied and returns <code>null</code> , then it is considered an error and the DSP construction fails.
SEE:	<code>#link &lt;sedsp&gt;</code>
EXAMPLE:	<code>function fileOpen( filename )</code>

---

---

```
{
    return Clib.fopen( filename, "wb" );
}
var connection = new DSP( fileOpen, "c:\tempfile.dat"
);
// This will call fileOpen and assign the result to
// connection.dspConnection.  If it was null,
// then the DSP connection will fail
```

---

### **DSP dspCloseConnection()**

---

**SYNTAX:** `dsp.closeConnection(connection)`

**WHERE:** `connection` - The original connection that was created with the `openFunction` passed to `new DSP()`

**RETURN:** `void`.

**DESCRIPTION:** This function is responsible for terminating the connection that was opened at the time the DSP object was created. This is an optional function, and if not supplied then nothing will be done with the connection. See the introduction, under [creating a DSP object](#), for an example of how to implement this function.

**SEE:** [#link <sedsp>, DSP\(\)](#)

---

### **DSP dspReceive()**

---

**SYNTAX:** `dsp.dspReceive(connection, buffer, bufferLength, timeout)`

**WHERE:** `connection` - The original connection that was returned from the `openFunction` passed to `new DSP()`

`buffer` - A buffer which is to be filled with data. This variable must be passed by reference (with the `&` operator).

`bufferLength` - The maximum amount of data to read

`timeout` - The maximum amount of time to wait (in milliseconds) for data to be ready for reading on the connection

**RETURN:** `number` - The number of bytes read, or -1 on error

**DESCRIPTION:** This function is responsible for getting data from the connection. This function should wait up to `timeout` milliseconds for data to be available on the connection. If there is no data available, then this function should return 0. Otherwise, the function should read up to `bufferLength` bytes from the connection and put the data into `buffer`. Note that this means that `buffer` must be passed by reference. If there is some sort of error, then this function should either throw an error, or return -1. See introduction, under [creating a DSP object](#), for an example of how to implement this function. Note that the function need not wait for the entire buffer to be filled, it should read only as much data as is available to be read.

**SEE:** [#link <sedsp>, DSP dspSend\(\)](#)

---

## DSP dspSend()

---

**SYNTAX:** `dsp.dspSend(connection, buffer, timeout)`  
**WHERE:** `connection` - The original connection that was returned from the `openFunction` passed to `new DSP()`  
`buffer` - The buffer to send  
`timeout` - The maximum amount of time to wait (in milliseconds) for data to be ready for writing on the connection

**RETURN:** `number` - The number of bytes written, or -1 on error

**DESCRIPTION:** This function is responsible for sending data across the connection (the one returned by the `openFunction` passed to the `DSP` constructor). Its behavior is similar to that of `dspReceive()`. It should wait up until `timeout` for data to be ready, and then send as much as possible along the connection (up to the length of `buffer`). If the timeout expires, the function should return 0. If there was some sort of error, then an error should be thrown, or -1 returned. Otherwise, the number of bytes written should be returned. Throwing an error is often more descriptive than the generic failure message. See introduction, under [creating a DSP object](#), for an example of how to implement this function.

**SEE:** `#link <sedsp>, DSP dspReceive()`

---

## DSP dspLoad()

---

**SYNTAX:** `dsp.dspLoad(code)`  
**WHERE:** `code` - String of code to load on the remote server

**RETURN:** `void`.

**DESCRIPTION:** This function loads the specified code into the global context on the remote server. Any code that you execute will remain on the remote server. This function is designed to load functions on the remote server so that they may be called by the client. This function does not wait for a return value from the host. As a consequence, remote errors will not be immediately reported. They will be reported next time a client routine (calling a function, getting/putting a value) queries the server. Note that if you wish to execute remote code and get a return value, the global `eval()` method for the server should be used, although the changes will not be permanent.

**SEE:** `#link <sedsp>`

**EXAMPLE:**

```
function foo() { Screen.writeln("Hello!"); }  
// This code will make "foo = new Function(...)"  
// to set up the function on the remote server.  
connection.dspLoad( "foo = " + ToSource(foo) );  
connection.foo();  
// foo is now a global function on the server
```

---

## DSP dspService()

---

**SYNTAX:** `dsp.dspService()`

---

---

RETURN: boolean - A value indicating whether the connection is still open.

DESCRIPTION: This is the main server-side function. Although it can be used by any DSP object, it is intended to be the server side of the client-server model. When called, it will wait until an incoming packet is received and then service that packet appropriately. The method will return `false` if the packet received was a close command, in which case the connection has been closed, and an explicit call to `dspClose` is not necessary. It is designed to be called repeatedly until the connection is closed.

SEE: `#link <sedsp>`

EXAMPLE: 

```
// Assume 'connection' is a valid connection
while( connection.dspService() )
    ;
// At this point, the connection has been
// successfully closed
```

---

### DSP `dspClose()`

---

SYNTAX: `dsp.dspClose()`

RETURN: `void`.

DESCRIPTION: This function closes the DSP connection. First, it sends a close command to the remote host, signaling that the connection is closing. It then calls the `dspCloseConnection` method if it exists, passing the original connection variable returned by the open function when this connection was created.

SEE: `#link <sedsp>`

EXAMPLE: `connection.dspClose();`

---

### DSP `dspGetValue()`

---

SYNTAX: `dsp.dspGetValue()`

RETURN: `variable` - remote value of the current DSP reference.

DESCRIPTION: This function provides an explicit way to convert a DSP reference into a value. Such conversion is done automatically when the reference is converted to a primitive, or a value is assigned to a reference. See the introduction, under [creating a DSP object](#), for more information on DSP references and getting remote values.

SEE: `#link <sedsp>`

EXAMPLE: 

```
var reference = connection.globalValue;
var value = connection.globalValue.dspGetValue();
reference = 5; // This will change the remote value
value = 6;
// This will change the local copy, not the remote
```

---

### DSP `dspSecurityInit()`

---

SYNTAX: `dsp.dspSecurityInit(secureVar)`

WHERE: `secureVar` - private storage for the DSP security. The member 'dsp' is preset to the DSP object. Remember, the DSP object can

---

---

	be seen by the running script, but not the secure variable itself.
RETURN:	void.
DESCRIPTION:	The dspSecurityInit function turns on security for a DSP object. This means when the remote client tries to run a script on your machine using DSP, it will be run with your security manager in effect. In the case of DSP, each security function (jseSecurityInit, jseSecurityTerm, and jseSecurityGuard) has an exactly corresponding function, i.e., dspSecurityInit, dspSecurityTerm, and dspSecurityGuard. In the security initialization function, you'll typically select some functions to be allowed, and let all others be vetoed.
SEE:	<a href="#">#link &lt;sedsp&gt;, DSP dspSecurityTerm(), DSP dspSecurityGuard()</a>
EXAMPLE:	<pre>function iDSP.dspSecurityGuard( conn ) {     myfunc.setSecurity(jseSecureAllow);     myotherfunc.setSecurity(jseSecureGuard); }</pre>

---

### **DSP dspSecurityTerm()**

---

SYNTAX:	<code>dsp.dspSecurityTerm(secureVar)</code>
WHERE:	secureVar - private storage for the DSP security.
RETURN:	void.
DESCRIPTION:	This function is typically not needed, but you can use it to cleanup anything you initialized in the DSP security initialization function.
SEE:	<a href="#">#link &lt;sedsp&gt;, DSP dspSecurityInit(), DSP dspSecurityGuard()</a>

---

### **DSP dspSecurityGuard()**

---

SYNTAX:	<code>dsp.dspSecurityGuard(secureVar, function, params)</code>
WHERE:	function - the function being called secureVar - private storage for the DSP security. params - whatever parameters are passed to the function
RETURN:	void.
DESCRIPTION:	If a DSP object is given a dspSecurityGuard function (exactly like any of the other DSP callback functions), when it tries to call any function not part of the script (i.e. one of your functions or a wrapper function), the security guard is called for approval. You must provide a dspSecurityInit for security to be activated. Only those functions the security initialization function marks as guarded will use this function.
SEE:	<a href="#">#link &lt;sedsp&gt;, DSP dspSecurityInit(), DSP</a>

---

## DSP object static properties

### DSP.remote

---

SYNTAX: `DSP.remote`

DESCRIPTION: This global property of the DSP object is used to make calls back to the remote client from within a function. When the first DSP object in a script is created, this gets assigned to that value. From then on, whenever a packet needs to be serviced, this value is set (and later restored) to the object representing the incoming connection. This allows for multiple connections, and lets the function easily call back the appropriate client. Note that within a `dspLoad` call, the client does not wait for a response, and so trying to call on the client will yield no result until the server is queried again.

SEE: `#link <sedsp>`

EXAMPLE: 

```
// Assume the client calls this:
serverConn.printRemote("hi");
// And the server side looks like this:
function printRemote( string )
{
    DSP.remote.Screen.write( string );
}
// This will print out "hi" on the client machine
```

---

---

# GD Link Library

## GD Object

```
title: GD Object
platform: All OS except Dos; All versions of SE
source: #link <gd>
```

The GD object provides a set of routines for manipulating GIF images.

### Point specifications

A number of GD routines expect a Point Specification as one of the parameters. This is a pseudo-type that can take one of several forms. It is either an object with two members, 'x' and 'y', representing the two coordinates of the point, or an array with two members, element 0 being the x coordinate and element 1 being the y coordinate. All of the following are equivalent:

```
var point1 = {x:1, y:2};
var point2 = [1, 2];
```

Note also that every routine can also have the x and y coordinates passed as separate parameters, so these are equivalent:

```
gd.getPixel( 1, 2 );
gd.getPixel( [1,2] );
```

As such, the Point object is really just a matter of convenience to help distinguish points as a unit.

### Font specifications

The character drawing routines expect a font parameter which describes the font to use. The font selection, though limited, should be enough for the basic purposes for which this library is used. Valid font types are the strings "*tiny*", "*small*", "*mediumBold*", "*large*", or "*giant*". Each one is a different size. *fontTiny* is 5x8, *fontSmall* is 6x12, *fontMediumBold* is 7x13, *fontLarge* is 8x16, and *fontGiant* is 9x15.

### Color styles

In addition to simple color indexes, all drawing routines can also take a color stype, which is a special string value that allows for more complex fills and shapes. The valid types are:

*"styled"* - Use the style specified with **GD setStyle()**. A style is a sequence of colors to be used when drawing lines. It is only valid for line-drawing routines, and is used to make dashed lines.

*"brushed"* - Use the brush specified with **GD setBrush()**. A brush is another GD image which is drawn instead of a regular pixel. Using transparent colors, it is possible to create a brush of any size.

*"styledBrushed"* - A combination of both "*styled*" and "*brushed*". The brush is used, but is only drawn when non-transparent pixels are encountered in the style.

*"tiled"* - Use the tile specified with **GD setTile()**. This style can only be used with fill routines. It uses the current tile, which can be any GD image, and fills the region with that tile, laying the images side-by-side sequentially.

## GD object instance methods

### GD()

---

**SYNTAX:** `new GD(x, y)`  
**WHERE:** `x` - Horizontal size, in pixels.  
`y` - Vertical size, in pixels.  
**RETURN:** object - a new GD object of the specified size.  
**DESCRIPTION:** The `x` and `y` parameters determine the horizontal and vertical size of the image, respectively. The object returned is a GD object.  
**SEE:** `#link <gd>`

---

### GD arc()

---

**SYNTAX:** `gd.arc(centerX, centerY, width, height, startDegree, endDegree, color)`  
`gd.arc(centerPoint, width, height, startDegree, endDegree, color)`  
**WHERE:** `centerX` - horizontal position of center.  
`centerY` - vertical position of center.  
`centerPoint` - center point specification.  
`height` - height of arc.  
`startDegree` - degree value of starting position in standard coordinate plane. Values greater than 360 are interpreted as modulo 360.  
`endDegree` - degree value of ending position in standard coordinate plane. Values greater than 360 are interpreted as modulo 360.  
`color` - color index to use for arc, or one of the strings "styled", "brushed", "styledBrushed".  
**RETURN:** void.  
**DESCRIPTION:** This method draws an arc in the specified format. The center position is specified, along with the width and the height. The arc is then draw between the two given degree values. A full ellipse can be drawn from degree 0 to degree 360, and a circle can be drawn in the same manner while setting `width` and `height` to be the same. If there is an out-of-bounds error or some other error, then the arc is not drawn at all.  
**SEE:** `#link <gd>`  
**EXAMPLE:**

```
// Draw a circle with a diameter of 16 pixels
// in the middle of the image
var gd = new GD(65, 65);
gd.arc( [32,32], 16, 16, 0, 360, 0 );
```

---

### GD blue()

---

SYNTAX:	<code>gd.blue(index)</code>
WHERE:	<code>index</code> - color index to look up.
RETURN:	number - blue component of the specified color index.
DESCRIPTION:	This method looks up the color indicated by <code>index</code> and returns the blue component of that color.
SEE:	<a href="#">#link &lt;gd&gt;</a> , <a href="#">GD red()</a> , <a href="#">GD green()</a>
EXAMPLE:	<pre>var index = gd.colorAllocate(0,100,200); gd.blue(index); // This will return 200</pre>

---

## GD boundsSafe()

---

SYNTAX:	<code>gd.boundsSafe(x, y)</code> <code>gd.boundsSafe(point)</code>
WHERE:	<code>x</code> - horizontal pixel location.  <code>y</code> - vertical pixel location.  <code>point</code> - Point specification. See <a href="#">GD getPixel()</a> for a description.
RETURN:	boolean - whether the specified coordinates are within bounds.
DESCRIPTION:	This method sees if the specified pixel location is within the bounds of the image. If so, then <code>true</code> is returned, <code>false</code> otherwise.
SEE:	<a href="#">#link &lt;gd&gt;</a>
EXAMPLE:	<pre>var gd = new GD(5,5); gd.boundsSafe( 4, 3 ); // True gd.boundsSafe( [4,5] ); // False gd.boundsSafe( {x:6,y:2} ) // False</pre>

---

## GD drawChar()

---

SYNTAX:	<code>gd.drawChar(font, x, y, char, color)</code> <code>gd.drawChar(font, point, char, color)</code>
WHERE:	<code>font</code> - Font specification  <code>x</code> - horizontal position of upper-left corner of character  <code>y</code> - vertical position of upper-left corner of character  <code>point</code> - Point specification.  <code>char</code> - The specified character to draw  <code>color</code> - color index or style to use
RETURN:	void.
DESCRIPTION:	This method draws a character in the image at the specified location in the appropriate font. If the coordinates are out of bounds, then no drawing is done. The reason that it is named 'drawChar' and not simply 'char' is that 'char' is a reserved keyword and an invalid variable name.
SEE:	<a href="#">#link &lt;gd&gt;</a> , <a href="#">GD charUp()</a> , <a href="#">GD string()</a>
EXAMPLE:	<pre>// Write "hi" at the starting position var gd = new GD(50,50);</pre>

---

---

```
gd.drawChar( GD.fontSmall, 5, 5, "h", 0 );
gd.drawChar( GD.fontSmall, [11,5], "i", 0 );
// This is the equivalent of GD.string()
// with the string "hi"
```

---

### **GD charUp()**

---

**SYNTAX:** `gd.charUp(font, x, y, char, color)`  
`gd.charUp(font, point, char, color)`

**WHERE:** font - Font specification

x - horizontal position of upper-left corner of character

y - vertical position of upper-left corner of character

point - point specification. See [GD getPixel\(\)](#) for a description.

char - specified character to draw

color - color index or style to use

**RETURN:** void.

**DESCRIPTION:** This method is exactly the same as [GD drawChar\(\)](#), except that the character is drawn vertically, pointing upwards.

**SEE:** [#link <gd>](#), [GD drawChar\(\)](#), [GD stringUp\(\)](#)

---

### **GD colorAllocate()**

---

**SYNTAX:** `gd.colorAllocate(red, green, blue)`

**WHERE:** red - Red value, from 0 to 255

green - Green value, from 0 to 255

blue - Blue value, from 0 to 255

**RETURN:** number - Color index of allocated color, or -1 if none available.

**DESCRIPTION:** This method searches through the color table for the next available color index, and sets it to be the supplied RGB color. If no color indexes are available, then -1 is returned. If the supplied RGB colors are invalid, a runtime error is generated. When creating a new image, the first time you call this function, you set the background color for the image.

**SEE:** [#link <gd>](#), [GD colorExact\(\)](#), [GD colorClosest\(\)](#), [GD colorDeallocate\(\)](#)

**EXAMPLE:**

```
var gd = new GD(10,10);
var index = gd.colorAllocate(255,255,255);
// index now points to white, and the background
// of the image is also white
```

---

### **GD colorClosest()**

---

**SYNTAX:** `gd.colorClosest(red, green, blue)`

**WHERE:** red - Red value, from 0 to 255

green - Green value, from 0 to 255

---

---

blue - Blue value, from 0 to 255

RETURN: number - index of the closest color to the one supplied.

DESCRIPTION: This method searches through the color table and finds the closest color to the one supplied. The algorithm uses Euclidian distance to calculate closeness. This function is most useful when unable to allocate a new color, and the closest must be used instead.

SEE: #link <gd>, [GD colorAllocate\(\)](#)

EXAMPLE: 

```
/* Attempt to allocate a specific color,
 * but if unable to (the image
 * has the maximum number of colors),
 * then attempt to find the closest
 * color as a suitable replacement
 */
var gd = GD.fromGif("test.gif");
var index;
if( -1 == (index = gd.colorAllocate(234,12,107)) )
    index = gd.colorClosest(234,12,107);
```

---

### **GD colorDeallocate()**

---

SYNTAX: `gd.colorDeallocate(color)`

WHERE: color - color index to deallocate.

RETURN: void.

DESCRIPTION: This method frees up the color at index `color` for later use. The color index will remain the same, but it may be re-allocated at any point and changed. Note that this function simply marks the color for reuse, so that the total colors allocated in the image still remains the same. If a call to `colorAllocate()` immediately follows this call, then the old index will be re-used for the new color, and all pixels within the image with that index will be altered as well.

SEE: #link <gd>, [GD colorAllocate\(\)](#)

---

### **GD colorExact()**

---

SYNTAX: `gd.colorExact(red, green, blue)`

WHERE: red - Red value, from 0 to 255

green - Green value, from 0 to 255

blue - Blue value, from 0 to 255

RETURN: number - The first index matching the supplied color, or -1 if it doesn't exist.

DESCRIPTION: This method searches through the color table and tries to find the first index whose red, green, and blue values are exactly equal to the supplied values. If no index is found, then -1 is returned.

SEE: #link <gd>, [GD colorClosest\(\)](#), [GD colorAllocate\(\)](#)

EXAMPLE: 

```
// Attempt to get the color,
```

---

---

```
// and create it if it does not exist
var gd = GD.fromGif("test.gif");
var index;
if( -1 == (index = gd.colorExact(1,1,1)) )
    index = gd.colorAllocate(1,1,1);
```

---

### **GD colorsTotal()**

---

SYNTAX: `gd.colorsTotal()`

RETURN: `void`.

DESCRIPTION: This method returns the total number of colors allocated in the current GD image. Note that colors deallocated with `colorDeallocate()` are still considered 'allocated', because they have simply been marked for reuse.

SEE: `#link <gd>`

---

### **GD colorTransparent()**

---

SYNTAX: `gd.colorTransparent(color)`

WHERE: `color` - color index to make transparent.

RETURN: `void`.

DESCRIPTION: This method sets the specified color index to be the transparent index. To indicate that there is to be no transparent color, the value -1 should be passed as the color index.

SEE: `#link <gd>`

EXAMPLE: 

```
var gd = new GD(64,64);
var index = gd.colorAllocate(0,0,0);
gd.colorTransparent(index);
// The background (and all black pixels)
// is transparent
```

---

### **GD copy()**

---

SYNTAX: `gd.copy(source, dstX, dstY, srcX, srcY, width, height)`  
`gd.copy(source, dstPoint, srcPoint, width, height)`

WHERE: `source` - A gd object to copy from

`dstX` - Horizontal destination pixel in current object

`dstY` - Vertical destination pixel in current object

`dstPoint` - Destination pixel in current object.

`srcX` - Horizontal source pixel in source object

`srcY` - Vertical source pixel in source object

`srcPoint` - Source pixel in source object.

`width` - Width of section to copy

`height` - Height of section to copy

RETURN: `void`.

---

---

DESCRIPTION:	This method copies a section from one GD image to another. The portion of <code>source</code> , starting at the specified point (which is the upper-left corner of the region) and extending <code>width</code> and <code>height</code> in either direction. This region is then copied to the current GD object at the specified location (which is again the upper-left corner of the region). In copying the region, this method attempts to preserve the colors of the original source as best as possible. The method first tries calling <code>colorExact()</code> on the current image, and if that doesn't work then <code>colorAllocate()</code> , and finally if that fails, then <code>colorClosest()</code> . If you specify the same source image as the current image, then the method will work appropriately as long as the regions do not overlap. If they do, then the result is <code>undefined</code> .
SEE:	<code>#link &lt;gd&gt;</code> , <a href="#">GD copyResized()</a>
EXAMPLE:	<pre>// Copy top-left 16x16 from "test.gif" // while attempting to preserve // necessary colors. var source = GD.fromGif("test.gif"); var dest = new GD( 16, 16 ); dest.copy( source, [0,0], [0,0], 16, 16 );</pre>

---

## **GD copyResized()**

---

SYNTAX:	<pre>gd.copyResized(source, dstX, dstY, srcX, srcY,                dstW, dstH, srcW, srcH) gd.copyResized(source, dstPoint, srcPoint, dstW,                dstH, srcW, srcH)</pre>
WHERE:	<p><code>source</code> - A gd object to copy from</p> <p><code>dstX</code> - Horizontal destination pixel in current object</p> <p><code>dstY</code> - Vertical destination pixel in current object</p> <p><code>dstPoint</code> - Destination pixel in current object.</p> <p><code>srcX</code> - Horizontal source pixel in source object</p> <p><code>srcY</code> - Vertical source pixel in source object</p> <p><code>srcPoint</code> - Source pixel in source object.</p> <p><code>dstW</code> - Width of region in current object</p> <p><code>dstH</code> - Height of region in current object</p> <p><code>srcW</code> - Width of region in source object</p> <p><code>srcH</code> - Height of region in source object</p>
RETURN:	<code>void</code> .
DESCRIPTION:	This method is very similar to <a href="#">GD copy()</a> , except that it has the additional option of resizing the image in the process of copying. This method will stretch or shrink the region as appropriate in order to fit in the destination area. Specifying the same destination and source sizes is the equivalent of calling <a href="#">GD copy()</a> . See <a href="#">GD copy()</a> for more description.

---

---

SEE: #link <gd>, [GD copy\(\)](#)

EXAMPLE: 

```
// Copy top-left 4x4 square from "test.gif"
// and magnify it four times
// to a size of 16x16 in the destination image
var source = GD.fromGif("test.gif");
var dest = new GD( 16, 16 );
dest.copyResized(source, [0,0], [0,0], 16, 16, 4, 4);
```

---

### **GD dashedLine()**

---

SYNTAX: `gd.dashedLine(x1, y1, x2, y2, color)`  
`gd.dashedLine(point1, point2, color)`

WHERE: `x1` - horizontal pixel location of starting point  
`y1` - vertical pixel location of starting point  
`x2` - horizontal pixel location of ending point  
`y2` - vertical pixel location of ending point  
`point1` - First point specification.  
`point2` - Second point specification.  
`color` - color index or style to use for drawing line

RETURN: `void`.

DESCRIPTION: This method is exactly the same as [GD line\(\)](#), except that a dashed line is drawn. This function is only for backwards compatibility, as much greater control is achieved by using the combination of [GD setStyle\(\)](#) and [GD line\(\)](#).

SEE: #link <gd>, [GD line\(\)](#), [GD setStyle\(\)](#)

EXAMPLE: 

```
var gd = new GD(10,10);
gd.dashedLine( [2,3], [9,7], 0 );

// The above code has been replaced by the following
var gd = new GD(10,10);
// Four pixel wide dash
gd.setStyle( [0, 0, 0, 0, -1, -1, -1, -1 ] );
gd.line( [2,3], [9,6], "styled" );
```

---

### **GD destroy()**

---

SYNTAX: `gd.destroy()`

RETURN: `void`.

DESCRIPTION: This method cleans up all the memory associated with this GD object. Once it has been called, the object is no longer valid.

SEE: #link <gd>

---

### **GD fill()**

---

SYNTAX: `gd.fill(x, y, color)`  
`gd.fill(point, color)`

WHERE: `x` - Horizontal position of starting pixel  
`y` - Vertical position of starting pixel

---

---

point - Point of starting pixel. See [GD getPixel\(\)](#) for a description

color - Fill color index or style

RETURN: void.

DESCRIPTION: This method is very similar to [GD fillToBorder\(\)](#), except that instead of filling until another color is hit, this method fills all pixels that are the same color as the original, until it hits any other color pixel. The pixels are changed to the color indicated by color.

SEE: [#link <gd>, GD fillToBorder\(\)](#)

EXAMPLE: 

```
/* Draw a circle with color index 1 and
 * a smaller one with color
 * index 3. The call to GD.fill() will fill
 * the inner circle with color
 * index 2. The fill will stop at first circle,
 * since it is not the
 * same color as the starting pixel.
 */
var gd = new GD(65, 65);
gd.arc( [32,32], 16, 16, 0, 360, 1 );
gd.arc( [32,32], 14, 14, 0, 360, 3 ); // will be
erased
gd.fill( [33,34], 2 );
```

---

### **GD filledPolygon()**

SYNTAX: `gd.filledPolygon(point1[, x2, y2[, ...], color)`

WHERE: pointN - Point specification for Nth point

xN - x coordinate of Nth point

yN - y coordinate of Nth point

color - color index or style to use for fill

RETURN: void.

DESCRIPTION: This method is exactly the same as [GD polygon\(\)](#), except that it fills in the polygon, managing intersections in the process.

SEE: [#link <gd>, GD polygon\(\)](#)

---

### **GD filledRectangle()**

SYNTAX: `gd.filledRectangle(x1, y1, x2, y2, color)`  
`gd.filledRectangle(point1, point2, color)`

WHERE: x1 - horizontal pixel location of first corner

y1 - vertical pixel location of first corner

x2 - horizontal pixel location of second corner

y2 - horizontal pixel location of second corner

point1 - First point specification.

point2 - Second point specification.

---

---

	color - color index or style to use for fill
RETURN:	void.
DESCRIPTION:	This method is exactly the same as <a href="#">GD rectangle()</a> , except that it fills the rectangle, instead of drawing an outline. As with <a href="#">GD rectangle()</a> , if either point is out of bounds, then no drawing is done.
SEE:	<a href="#">#link &lt;gd&gt;</a> , <a href="#">GD rectangle()</a> , <a href="#">GD filledPolygon()</a>

---

### **GD fillToBorder()**

---

SYNTAX:	<code>gd.fillToBorder(x, y, border, color)</code> <code>gd.fillToBorder(point, border, color)</code>
WHERE:	x - Horizontal position of starting pixel  y - Vertical position of starting pixel  point - Point specification of starting pixel.  border - Index border color to stop at  color - Fill color or style index
RETURN:	void.
DESCRIPTION:	This method fills the image with the selected color, until it hits a border with the color specified by <code>border</code> . <code>border</code> must be a color index, not one of the styled colors. <code>color</code> can be anything.
SEE:	<a href="#">#link &lt;gd&gt;</a> , <a href="#">GD fill()</a>
EXAMPLE:	<pre>/* Will draw a circle with color index 1,  * and then fill it with color  * index 2. The fill will stop  * at the specified border, which means that  * the second circle drawn, using color index 3,  * will be erased as the  * outer circle is filled.  */ var gd = new GD(65, 65); gd.arc( [32,32], 16, 16, 0, 360, 1 ); gd.arc( [32,32], 14, 14, 0, 360, 3 ); // will be erased gd.fillToBorder( [33,34], 1, 2 );</pre>

---

### **GD getInterlaced()**

---

SYNTAX:	<code>gd.getInterlaced()</code>
RETURN:	boolean - Whether this image is interlaced.
DESCRIPTION:	If the current image has the interlace flag set, then this method returns <code>true</code> . Otherwise, it returns <code>false</code> .
SEE:	<a href="#">#link &lt;gd&gt;</a> , <a href="#">GD interlace()</a>

---

### **GD getPixel()**

---

SYNTAX:	<code>gd.getPixel(x, y)</code> <code>gd.getPixel(point)</code>
---------	---

---

---

WHERE:	x - horizontal position of pixel, measured from left y - vertical position of pixel, measured from top point - A point specification.
RETURN:	number - a color index indicating the color at the selected pixel.
DESCRIPTION:	This method accesses the pixel at position (x, y), and returns the color of that pixel. If the pixel coordinates are out of bounds, then zero is returned.
SEE:	<a href="#">#link &lt;gd&gt;</a> , <a href="#">GD SetPixel()</a>
EXAMPLE:	<pre>var gd = GD.fromGif("test.gif"); gd.getPixel(0,0); gd.getPixel( [0,0] ); gd.getPixel( {x:0,y:0} );</pre>

---

### **GD getTransparent()**

---

SYNTAX:	<code>gd.getTransparent()</code>
RETURN:	number - The color index of the current transparent color for this image.
DESCRIPTION:	This method looks up the transparent color that was set by <code>GD transparent()</code> or read from the file originally.
SEE:	<a href="#">#link &lt;gd&gt;</a> , <a href="#">GD transparent()</a>

---

### **GD green()**

---

SYNTAX:	<code>gd.green(index)</code>
WHERE:	index - The color index to look up
RETURN:	number - The green component of the specified color index
DESCRIPTION:	This method looks up the color indicated by <code>index</code> and returns the green component of that color.
SEE:	<a href="#">#link &lt;gd&gt;</a> , <a href="#">GD blue()</a> , <a href="#">GD red()</a>

---

### **GD height()**

---

SYNTAX:	<code>gd.height()</code>
RETURN:	number - The height of the image
DESCRIPTION:	This method returns the height of the current GD image
SEE:	<a href="#">#link &lt;gd&gt;</a>

---

### **GD interlace()**

---

SYNTAX:	<code>gd.interlace(flag)</code>
WHERE:	flag - A boolean value indicating whether this image is interlaced or not
RETURN:	void.
DESCRIPTION:	This method sets the interlace flag for the current image. If the

---

---

flag parameter is `true`, then the image is interlaced, otherwise it is not. Interlaced GIF images allow views to gradually fade in the image, rather than having to read in the whole file and then display it. This flag only affects the image once it is saved as a GIF file. It has no affect on any other methods. Viewers which don't support interlacing will still be able to display the image, it will just appear all at once like any other image.

SEE: [#link <gd>](#), [GD getInterlaced\(\)](#)

---

## GD line()

---

SYNTAX: `gd.line(x1, y1, x2, y2, color)`  
`gd.line(point1, point2, color)`

WHERE: `x1` - horizontal pixel location of starting point  
`y1` - vertical pixel location of starting point  
`x2` - horizontal pixel location of ending point  
`y2` - vertical pixel location of ending point  
`point1` - First point specification.  
`point2` - Second point specification.  
`color` - color index or style to use for drawing line

RETURN: `void`.

DESCRIPTION: This method draws a line using color index `color`, starting from position (`x1`, `y1`) and going to position (`x2`, `y2`). Alternatively, the line is drawn from `point1` to `point2`, if the coordinates are given in this manner. If either coordinate is out of bounds, then no drawing is done.

SEE: [#link <gd>](#), [GD dashedLine\(\)](#)

---

## GD polygon()

---

SYNTAX: `gd.polygon(point1[, x2, y2, ...], color)`

WHERE: `pointN` - Point specification for Nth point  
`xN` - x coordinate of Nth point  
`yN` - y coordinate of Nth point  
`color` - color index or style to use for line

RETURN: `void`.

DESCRIPTION: This method draws a polygon by connecting sequential points with lines. The parameters are either a pair of parameters indicating the two coordinates of the point, or a point specification type. A point type can either be an array with two elements, element 0 being the x coordinate and element 1 being the y coordinate, or an object with members 'x' and 'y', representing the x and y coordinates.

---

---

SEE: #link <gd>, [GD filledPolygon\(\)](#)

EXAMPLE: 

```
// Draw a rectangle
function myRectangle(gd,x1,y1,x2,y2,color)
{
    gd.polygon([x1,y1], x1, y2, {x:x2,y:y2}, [x2,y1],
               [x1,y1], color);
}
```

---

## **GD rectangle()**

---

SYNTAX: `gd.rectangle(x1, y1, x2, y2, color)`  
`gd.rectangle(point1, point2, color)`

WHERE: `x1` - horizontal pixel location of first corner  
`y1` - vertical pixel location of first corner  
`x2` - horizontal pixel location of second corner  
`y2` - horizontal pixel location of second corner  
`point1` - First point specification.  
`point2` - Second point specification.  
`color` - color index or style to use for drawing line

RETURN: `void`.

DESCRIPTION: This method draws a rectangle with one corner located at position (`x1`, `y1`) and the other at position (`x2`, `y2`). The color used is specified by the `color` parameter. Alternatively, the coordinates can be specified with the point format. If either corner is out of bounds, then no drawing is done. Note that this is a shorthand function, as this can be accomplished in several other ways.

SEE: #link <gd>, [GD filledRectangle\(\)](#), [GD polygon\(\)](#)

EXAMPLE: 

```
var gd = new GD(10,10);
gd.rectangle( 4, 5, 8, 9, 0 );

// is equivalent to:
var gd = new GD(10,10);
gd.line( [4,5], [8,5], 0 );
gd.line( [4,9], [8,9], 0 );
gd.line( [4,5], [4,9], 0 );
gd.line( [8,5], [8,9], 0 );

// which is also equivalent to:
var gd = new GD(10,10);
gd.polygon( [ [4,5], [8,5], [4,9], [8,9] ], 0 );
```

---

## **GD red()**

---

SYNTAX: `gd.red(index)`

WHERE: `index` - The color index to look up

RETURN: `number` - The red component of the specified color index

DESCRIPTION: This method looks up the color indicated by `index` and returns the red component of that color.

---

---

SEE: [#link <gd>](#), [GD blue\(\)](#), [GD green\(\)](#)

---

## GD setBrush()

---

SYNTAX: `gd.setBrush(brush)`

WHERE: `brush` - A GD image to use as the current brush in this image

RETURN: `void`.

DESCRIPTION: This method sets the current brush for this image to be the image specified by `brush`. This image is then used for drawing when the "brushed" string is used as a color parameter to a drawing function. This method attempts to preserve the colors of the brush in the current image, including the transparent color. Transparent pixels are not draw when using the brush, allowing for brushes of any shape. The original brush must remain a valid image. Once `destroy()` has been called on the supplied brush, the style "brushed" can no longer be used until another brush is set. Note that because this can allocate colors in the image, do not set the brush if you won't be using it, because the color table could fill up quickly.

SEE: [#link <gd>](#), [GD setTile\(\)](#)

EXAMPLE: 

```
var brush = GD.fromGif("brush.gif");
var gd = new GD(64,64);
gd.setBrush( brush );
gd.line( [16,3], [52,45], "brushed" );
brush.destroy();
```

---

## GD setPixel()

---

SYNTAX: `gd.setPixel(x, y, color)`  
`gd.setPixel(point, color)`

WHERE: `x` - horizontal position of pixel, measured from left

`y` - vertical position of pixel, measured from top

`point` - A point specification.

`color` - index into color table

RETURN: `void`.

DESCRIPTION: This method sets the designated pixel to the appropriate color. If either `x` or `y` is out of bounds, or if `color` is not a valid color index, then nothing is done.

SEE: [#link <gd>](#), [GD getPixel\(\)](#), [GD colorAllocate\(\)](#)

EXAMPLE: 

```
var gd = new GD(4,4);
var black = gd.colorAllocate(0,0,0);
gd.setPixel(0,0,black);
```

---

## GD setStyle()

---

SYNTAX: `gd.setStyle(style)`

WHERE: `style` - style to set for current image.

---

---

**RETURN:** void.

**DESCRIPTION:** This method sets the current style for this image, which is used whenever the string "styled" is passed as a color index parameter to a drawing function. The parameters to the method is a list of pixels, which are color indexes or the special value -1, which indicates a transparent pixel. When drawing lines or a series of pixels, the drawing methods cycle through the sequence defined in the current style and applies the color to each successive pixel. If the value of -1 is used, then no color is applied and the background remains.

**SEE:** #link <gd>, [GD setBrush\(\)](#), [GD setTile\(\)](#)

**EXAMPLE:**

```

/* Create a Red, Green, Blue,
 * dashed line from the upper left
 * corner of the image to the lower right corner.
 * Each dash will be 3
 * pixels wide, and there will be 3 pixels
 * of space in between.
 */

var gd = new GD(64,64);
var red = gd.colorAllocate( 255, 0, 0 );
var green = gd.colorAllocate( 0, 255, 0 );
var blue = gd.colorAllocate( 0, 0, 255 );
gd.setStyle(red, red, red,
            -1, -1, -1,
            green, green, green,
            -1, -1, -1,
            blue, blue, blue,
            -1, -1, -1 );
gd.line( [0,0], [63,63], "styled" );

```

---

## **GD setTile()**

---

**SYNTAX:** gd.setTile(tile)

**WHERE:** tile - A GD image to use as the repeating tile for this image

**RETURN:** void.

**DESCRIPTION:** This method sets the current tile for this image in a manner similar to [GD setBrush\(\)](#). This tile image is then used whenever the style "tiled" is used as a color parameter in a function. The "tiled" style only works when calling a filling function, such as [GD fill\(\)](#) or [GD filledPolygon\(\)](#). This method attempts to preserve the colors of the original tile, by finding exact colors, allocating new colors, or finding the closest color if necessary. Transparent pixels in the image allow the underlying image to be shown through. Once the tile is set with setTile(), the original tile must be retained as long as the image is being used. Otherwise, the result is undefined.

**SEE:** #link <gd>, [GD setBrush\(\)](#)

**EXAMPLE:**

```

var tile = GD.fromGif("tile.gif");
var gd = new GD(64,64);
gd.setTile( tile );
gd.filledRectangle( [0,0], [63,63], "tiled" );

```

---

---

```
tile.destroy();
```

---

## GD string()

---

**SYNTAX:** `gd.string(font, x, y, char, color)`  
`gd.string(font, point, char, color)`

**WHERE:** font - Font specification to use

x - horizontal position of upper-left corner of character

y - vertical position of upper-left corner of character

point - Point specification. See [GD getPixel\(\)](#) for a description.

string - The string to draw.

color - color index or style to use for string

**RETURN:** void.

**DESCRIPTION:** This method draws a string on the current image, at the specified location and in the appropriate color. If the coordinates are out of bounds, then no drawing is done.

**SEE:** [#link <gd>](#), [GD drawChar\(\)](#), [GD stringUp\(\)](#)

---

## GD stringUp()

---

**SYNTAX:** `gd.stringUp(font, x, y, char, color)`  
`gd.stringUp(font, point, char, color)`

**WHERE:** font - Font specification to use

x - horizontal position of upper-left corner of character

y - vertical position of upper-left corner of character

point - Point specification. See [GD getPixel\(\)](#) for a description.

string - The string to draw.

color - color index or style to use for string

**RETURN:** void.

**DESCRIPTION:** This method is exactly the same as [GD string\(\)](#), except that this method draws the string vertically, facing upwards.

**SEE:** [#link <gd>](#), [GD charUp\(\)](#), [GD string\(\)](#)

---

## GD toGd()

---

**SYNTAX:** `gd.toGd(filename)`

**WHERE:** filename - Name of file to output to

**RETURN:** boolean - Whether the operation was successful

**DESCRIPTION:** This method outputs the gd object to the file in the native format of the library, which is unreadable by any other program, but can be read and written quickly. It is mostly used to store a commonly used base-image in native format, which can then be worked with from there.

---

---

SEE: #link <gd>, [GD.fromGif\(\)](#)

---

### **GD toGif()**

---

SYNTAX: `gd.toGif(filename)`  
WHERE: filename - Name of file to output to  
RETURN: boolean - Whether the operation was successful.  
DESCRIPTION: This method compresses the GIF data in the appropriate manner, and outputs the contents of the image to the specified file in GIF form.  
SEE: #link <gd>, [GD.toGd\(\)](#), [GD.fromGif\(\)](#)

---

### **GD width()**

---

SYNTAX: `gd.width()`  
RETURN: number - The width of the image  
DESCRIPTION: This method returns the width of the current GD image  
SEE: #link <gd>, [GD.height\(\)](#)

---

## **GD object static methods**

### **GD.fromGd()**

---

SYNTAX: `GD.fromGd(filename)`  
WHERE: filename - name of GD file to open.  
RETURN: object - new GD object with the contents of the specified file, or `null` if there was an error.  
DESCRIPTION: This method attempts to open the specified GD file, and then reads in the data. A GD file is one created with the `toGd()` method, and is written in the library's native format. If there is an error opening the file or reading the data, then `null` is returned.  
SEE: #link <gd>, [GD.fromGif\(\)](#), [GD.toGd\(\)](#)

---

### **GD.fromGif()**

---

SYNTAX: `GD.fromGif(filename)`  
WHERE: filename - name of GIF file to open.  
RETURN: object - new GD object with the contents of the file, or `null` if there was an error.  
DESCRIPTION: This method attempts to open the specified file, and then attempts to read in the GIF data. If there is an error opening the file or reading the data, then `null` is returned. Otherwise, the method constructs a new GIF object whose content is the GIF read from the file.

---

---

SEE: #link <gd>, [GD.fromGd\(\)](#), [GD toGif\(\)](#)

---

### **GD.fromXbm()**

---

SYNTAX: `GD.fromXbm(filename)`

WHERE: filename - name of XBM file to open.

RETURN: object - new GD object with the contents of the specified file, or null if there was an error.

DESCRIPTION: This method attempts to open the specified XBM file, and then reads in the data. If there is an error opening the file or reading the data, then null is returned.

SEE: #link <gd>, [GD.fromGif\(\)](#)

---

---

# MD5 Checksum Link Library

The md5 object provides a simple means of calculating checksums based on the md5 algorithm, a well-known and accepted method.

## md5 Object

platform: Mac, OS2, Windows, all versions of SE  
source: #link <md5>

## md5 object instance methods

### md5()

---

SYNTAX: `new md5()`

RETURN: `object` - a new md5 checksum object.

DESCRIPTION: This method creates a new object, and initializes it to be used for md5 sum computation. MD5 is an old, well-established checksum calculation formula that is still used for File download verification. The checksum verifies the integrity of the data, because if any bit is changes in the source, then the checksum will be drastically different.

SEE: #link <md5>

---

### term()

---

SYNTAX: `md5.term()`

RETURN: `buffer` - The computed checksum for this md5 object

DESCRIPTION: This method MUST be called in order to correctly dispose of the md5 object. It returns a buffer, 16 bytes long, representing the md5 checksum for this object. It also frees up any memory being used by the object.

SEE: #link <md5>

EXAMPLE: 

```
var md5sum = new md5();
md5.update("hi");
var digest = md5.term();
// digest is now equal to the checksum of "hi"
```

---

### update()

---

SYNTAX: `md5.update(buffer[, length])`

WHERE: `buffer` - A string or buffer of data to add into this checksum

`length` - Length of data to be added. If not supplied, then the length of buffer is used.

RETURN: `void`.

DESCRIPTION: This method adds the supplied buffer into the running md5 checksum. If `length` is greater than the length of `buffer`, then the buffer is expanded as if filled with `null` bytes.

---

---

SEE: [#link <md5>](#)

EXAMPLE: 

```
var md5sum = new md5();
md5sum.update("hello");
md5sum.update(", world!",4);
md5sum.term(); // Return the checksum of "hello, wo"
```

---

---

# SEDBC Link Library

The link library, *sedbc*, has methods and properties for working with a database in ScriptEase. These methods and properties provide a high-level interface for working with ODBC databases. The Database object allows the user to create a connection to a database which can then be queried, manipulated, and so forth through direct SQL statements or by the Cursor object. SQL statements stored inside the database are known as stored procedures and can be called using the Stproc object, allowing for the use of complex database-specific procedures from a script. Finally, true ease of use is provided by the SimpleDataset object, which is a combination of a Database object and a Cursor object. As a package, *sedbc* allows a script to have detailed, low-level control of an ODBC database through SQL statements and easy to use, high-level routines at the same time.

## Cursor object

```
platform: Win32; all versions of SE
source: #link <sedbc>
```

A Cursor object represents a database cursor for a specified SQL SELECT statement or specified database table.

A Cursor is a structure, created from a database table, which represents a subset of that table. When performing a query on a database, the results of the query are returned as a Cursor.

A Cursor object can be used to perform the following operations:

- Modify data in a database table.
- Navigate in a database table.
- Customize the display of the virtual table returned by a database query.

A Cursor object can be constructed in the following manners:

- The cursor method of a database object.
- The table method of a database object.
- The cursor method of an Stproc object.

There is no need to call a Cursor constructor.

A Cursor object has the notion of a "current" row. When operations are performed on a Cursor, they usually affect this row. The current row can be moved forward and backward through a Cursor using the `next` and `previous` methods, respectively. Similarly, the `first` and `last` methods set the current row to the first or last row in the cursor. Each of these methods will return `false` if the desired row does not exist within the Cursor. Thus, if the Cursor does not have any rows in it (perhaps because the SELECT statement used to create the cursor did not return any results), each of these methods will return `false`. Don't forget to check for this condition!

**Important** - A Cursor does not guarantee the order or positioning of its rows. For example, if a row is added to a Cursor, there is no way of knowing where that row will actually appear within in the cursor. Thus, do not make any assumptions about the ordering of rows within the Cursor. When finished with a

Cursor object, use the `close` method to close it and release the memory it uses. If a database connection that has an open Cursor is released, the runtime engine waits until that Cursor is closed before actually releasing the connection to the database, so it is important to remember to close Cursors. If a Cursor has not been not explicitly closed using the `close` method by the time the associated Database or DbPool object goes out of scope, the runtime engine will try to close it. This may tie up system resources unnecessarily and/or lead to unpredictable results. Use the `prototype` property of the Cursor class to add a property to all Cursor instances. The addition applies to all Cursor instances running in all applications on the server, not just the application that made the change. This allows the capabilities of the object to be expanded for the entire server.

## Cursor Instance Properties

The properties of Cursor objects vary from instance to instance. Each Cursor object has a property for each named column in the Cursor. Thus, when a Cursor is created, it acquires a property for each column in the virtual table, as determined by the `SELECT` statement.

**Note** - Unlike other properties in JavaScript, cursor properties corresponding to column names are not case sensitive, because SQL is not case sensitive and some databases are not case sensitive.

Properties of a Cursor object can be referred to as elements of an array. The 0-index array element corresponds to the first column, the 1-index array element corresponds to the second column, and so on.

`SELECT` statements can retrieve values that are not columns in the database, such as aggregate values and SQL expressions. Display these values by using the Cursor's property array index for the value.

### Cursor filter

---

SYNTAX: `cursor.filter`

DESCRIPTION: A property containing a conditional expression that determines which subset of rows is retrieved by a cursor. This expression is a string containing the `WHERE` clause of an SQL statement describing the rows to be included. The string does not include the reserved word `WHERE`, however. Initially, the filter property value is set to the empty string, indicating that all of the Cursor rows are to be retrieved. Call `reload` after changing the filter to update the contents of the Cursor.

SEE: [#link <sedbc>](#), [Cursor reload\(\)](#)

```
EXAMPLE: // assume 'database' is a valid Database object
var curs = database.table("customer")

// Set cursor filter so that the Cursor
// only retrieves objects
// whose 'City' field is set to 'Berlin'
curs.filter = "City = 'Berlin'";

// Reload the cursor
err = curs.reload();
```

---

### Cursor sort

---

**SYNTAX:** `cursor.sort`

**DESCRIPTION:** A property containing the sort order of a cursor. The Cursor sort order will determine the order that the rows are returned in when iterating the Cursor. The sort property is a string that contains the ORDER BY clause of an SQL statement. It does not include the reserved word ORDER BY, however. Initially, the sort property is set to the empty string, and, therefore, no item sort order is guaranteed. Call `reload` after changing the sort order to update the contents of the Cursor.

**SEE:** [#link <sedbc>](#), [Cursor reload\(\)](#)

**EXAMPLE:**

```
// assume 'database' is a valid Database object
var curs = database.table("customer")

// Set sort order so that the Cursor is sorted
// first by the
// 'city' field, and, for records
// with the same 'city' value,
// descending by the field 'name'.
curs.sort = "city, name DESC";

// Reload the cursor
err = curs.reload();
```

---

## Cursor Instance Methods

### Cursor close()

---

**SYNTAX:** `cursor.close()`

**RETURN:** number - 0 if the call was successful; otherwise, a nonzero status code based on the error message produced by the database. If the method returns a nonzero status code, use the associated `Database majorErrorCode` and `majorErrorMessage` methods to interpret the meaning of the error.

**DESCRIPTION:** The `close` method closes a cursor or result set and releases the memory it uses. If a cursor is not explicitly closed using the `close` method, it will automatically be closed by the runtime engine when the corresponding client object goes out of scope.

**SEE:** [#link <sedbc>](#), [Database majorErrorCode\(\)](#), [Database minorErrorCode\(\)](#)

**EXAMPLE:** `err = curs.close()`

---

### Cursor columnName()

---

**SYNTAX:** `cursor.columnName(n)`

**WHERE:** `n` - zero-based integer corresponding to the column in the query. The first column in the result set is 0, the second is 1, and so on.

**RETURN:** string - the name of column number `n` in the cursor.

**DESCRIPTION:** Given a column number, `columnName()` returns the name of the column.

When using SELECT statements with wildcards (\*) to select all

---

---

the columns in a table, the `columnName` method does not guarantee the order in which it assigns numbers to the columns. Thus, use `columnName` to find which name corresponds to which column number.

SEE: [#link <sedbc>, Cursor columns\(\)](#)

EXAMPLE: 

```
// assume 'database' is a valid, open Database object
var curs = database.cursor(SELECT * FROM customer);

// get the name of the first column in the cursor
header = customerSet.columnName(0);
```

---

### Cursor columns()

---

SYNTAX: `cursor.columns()`

RETURN: number - columns in a Cursor object.

DESCRIPTION: This function returns the number of named and unnamed columns that are present in the given Cursor.

SEE: [#link <sedbc>, Cursor columnName\(\)](#)

EXAMPLE: 

```
numCols = curs.columns();
```

---

### Cursor deleteRow()

---

SYNTAX: `cursor.deleteRow()`

RETURN: number - 0 if the call was successful; otherwise, a nonzero status code based on the error message produced by the database. If the method returns a nonzero status code, use the associated Database's `majorErrorCode` and `majorErrorMessage` methods to interpret the meaning of the error.

DESCRIPTION: This function, only available on updatable cursors, deletes the current row from the Database object.

SEE: [#link <sedbc>, Database commitTransaction\(\), Database rollbackTransaction\(\)](#)

EXAMPLE: 

```
// assume 'database' is a valid Database object
var curs = database.table("customer");

// delete all rows from the Database
// where City is "Malden"
while (curs.next())
{
    if(curs.City == "Malden")
        err = curs.deleteRow();
}
database.commitTransaction();
```

---

### Cursor first()

---

SYNTAX: `cursor.first()`

RETURN: boolean - false if the cursor is empty or if cursor is forward-only cursor and the current row is not the first row, otherwise true.

DESCRIPTION: This method moves the current row to the first row in the Cursor

---

---

and returns `true` so long as there is a first row. Note that if the cursor is empty, this method always returns `false`. Also note that, if the cursor does not allow backwards movement of the current row, `false` will be returned.

SEE: [#link <sedbc>](#), [Cursor next\(\)](#), [Cursor previous\(\)](#), [Cursor last\(\)](#)

EXAMPLE: 

```
// assume 'database' is a valid Database object
var curs = database.table("customer");

// set the current row to the first row in the Cursor
curs.first();
```

---

## Cursor insertRow()

---

SYNTAX: `cursor.insertRow()`  
RETURN: number - 0 if the call was successful; otherwise, a nonzero status code based on the error message produced by the database. If the method returns a nonzero status code, use the associated Database's `majorErrorCode` and `majorErrorMessage` methods to interpret the meaning of the error.

DESCRIPTION: This function, only available on undatable cursors, inserts a row into the associated database table. The location of the inserted row may vary depending on the database vendor's implementation, and thus row ordering is not guaranteed. There are several ways to specify values for the row being inserted:

Explicitly assigning values to each column in the cursor and then calling `insertRow`.

Choosing to a row using the `next` or `previous` methods, changing the values of some of the columns and then calling `insertRow`. Columns that were not explicitly assigned values will receive values from that initially chosen row.

Do not choose a row with `next` or `previous` and call `insertRow`. Since there is no current row in this case, all of the columns for the new row will be `null`.

Any columns in the cursor that contain unassigned values when `insertRow` is called will be `null` in the new row.

SEE: [#link <sedbc>](#), [Cursor next\(\)](#), [Cursor previous\(\)](#), [Database commitTransaction\(\)](#), [Database rollbackTransaction\(\)](#)

EXAMPLE: 

```
// assume 'database' is a valid Database object
var curs = database.table("customer");

// choose the first row to act as a "template"
// for the new row
curs.next();

// plug in some values for the new row
curs.Name = "Fred Flintstone";
curs.City = "Bedrock";

// add the row to the database
err = curs.insertRow();
```

---

---

```
database.commitTransaction();
```

---

### Cursor last()

---

**SYNTAX:** `cursor.last()`  
**RETURN:** `boolean` - `false` if the cursor is empty; otherwise `true`.

**DESCRIPTION:** This method moves the current row to the last row in the Cursor and returns `true` so long as there is a last row. Note that if the cursor is empty, this method always returns `false`.

**SEE:** #link <sedbc>, [Cursor next\(\)](#), [Cursor previous](#), [Cursor first\(\)](#)

**EXAMPLE:**

```
// assume 'database' is a valid Database object
var curs = database.table("customer");

// set the current row to the last row in the Cursor
curs.last();
```

---

### Cursor next()

---

**SYNTAX:** `cursor.next()`  
**RETURN:** `boolean` - `false` if the current row is the last row; otherwise `true`.

**DESCRIPTION:** The current row of a Cursor is initially positioned "before" the first row. Using the `next` method, the current row can be moved forwards through the records in the Cursor. The `next` method moves the pointer and returns `true` as long as there is another row available. When the current row has reached the last row of the Cursor, `next` returns `false`. Note that, in the event of an empty Cursor, this method will always return `false`.

**SEE:** #link <sedbc>, [Cursor previous\(\)](#), [Cursor first\(\)](#), [Cursor last\(\)](#)

**EXAMPLE:**

```
// assume 'database' is a valid Database object
var curs = database.cursor("select * from customer",
                           true);

// visit each object in the cursor
while (curs.next())
    ;
```

---

### Cursor previous()

---

**SYNTAX:** `cursor.previous()`  
**RETURN:** `boolean` - `false` if the current row is the first row; otherwise `true`.

**DESCRIPTION:** Using the `previous` method, the current row can be moved backwards through the records in the Cursor. The `previous` method moves the pointer and returns `true` as long as there is another row available. When the current row has reached the first row of the Cursor, `next` returns `false`. Note that, in the event of an empty Cursor, this method will always return `false`.

**SEE:** #link <sedbc>, [Cursor next\(\)](#), [Cursor first\(\)](#), [Cursor last\(\)](#)

**EXAMPLE:** `// assume 'database' is a valid Database object`

---

---

```
var curs = database.cursor("select * from customer",
                           true);

// set the current row to the last row in the cursor
curs.last();

// visit each object in the cursor, backwards
while (curs.previous())
    ;
```

---

### Cursor reload()

---

**SYNTAX:** `cursor.reload()`

**RETURN:** number - 0 if the call was successful; otherwise, a nonzero status code based on the error message produced by the database. If the method returns a nonzero status code, use the associated Database's `majorErrorCode` and `majorErrorMessage` methods to interpret the meaning of the error.

**DESCRIPTION:** Requeries the database and recreates the rows of the cursor, taking into account the filter and sort properties of the Cursor.

**SEE:** [#link <sedbc>](#), [Database majorErrorCode\(\)](#), [Database minorErrorCode\(\)](#), [Cursor sort](#), [Cursor filter](#)

**EXAMPLE:**

```
// assume 'curs' is a valid Cursor object
// Change sort order of the cursor rows
curs.sort = "Year";

// reload the cursor's contents
err = cursor.reload();
```

---

### Cursor updateRow()

---

**SYNTAX:** `cursor.updateRow()`

**RETURN:** number - 0 if the call was successful; otherwise, a nonzero status code based on the error message produced by the database. If the method returns a nonzero status code, use the associated Database's `majorErrorCode` and `majorErrorMessage` methods to interpret the meaning of the error.

**DESCRIPTION:** This method uses the values in the current row of an undatable cursor to modify a row in a table. Before an `updateRow` can be performed, make sure the `next` method has been called at least once, so that the current row of the Cursor is assigned.

To update a row in a database table, assign values to columns in the current row of the cursor, and call `updateRow`. Column values that are not explicitly assigned are not changed by the `updateRow` method.

**SEE:** [#link <sedbc>](#), [Cursor next\(\)](#), [Cursor previous\(\)](#), [Database commitTransaction\(\)](#), [Database rollbackTransaction\(\)](#)

**EXAMPLE:**

```
// assume 'database' is a valid Database object
var curs = database.table("customer");

// choose the first row to be updated
curs.next();
```

---

---

```
// update the values for the new row
curs.Paid = False;

// update the row in the Cursor
curs.updateRow();
database.commitTransaction();
```

---

## Database Object

platform: Win32; all versions of SE  
source: #link <sedbc>

**The Database object allows an application to access and interact with a relational database.**

Description of the Database object

Use the database object to connect to a remotely stored relational database stored on a server.

The database object can be used to perform the following tasks on a relational database:

- Execute SQL statements and queries on the database server
- Iterate the results of a query in order to process or display them
- Manage database transactions
- Run stored procedures

When closing down a database, be sure to close any associated open cursors, result sets, and stored-procedure objects, or else unpredictable results may occur.

## Database transactions

A transaction is a group of database actions that are performed together. Either all the actions succeed together or they all fail together. When a group of database actions is made permanent, it is called committing a transaction. Rolling back a transaction cancels all of the actions of a non-committed transaction.

Explicit transaction control is available for any set of actions using the `beginTransaction`, `commitTransaction`, and `rollbackTransaction` methods. If transactions are not controlled explicitly, the runtime engine uses the underlying database's autocommit feature to treat each database modification as a separate transaction. Each statement is either committed or rolled back immediately, based on the success or failure of the individual statement. Explicitly managing transactions overrides this default behavior.

NOTE: When making changes to a database, it is recommended that explicit transaction control be used. If not, the database may report errors. However, even if errors are not specifically reported, data integrity cannot be guaranteed unless explicit transactions are used. In addition, any time a `Cursors` object is used to update a database, it is also recommended that explicit transactions be used to ensure the consistency of the data.

For the database object, the scope of a transaction is limited to lifetime of the connection. If the database object is disconnected before calling

`commitTransaction` or `rollbackTransaction` method, then the transaction is automatically rolled back.

---

### Database `beginTransaction()`

---

**SYNTAX:** `database.beginTransaction()`

**RETURN:** number - 0 if the call was successful; otherwise, a nonzero status code based on the error message produced by the database. If the method returns a nonzero status code, use the `majorErrorCode` and `majorErrorMessage` methods to interpret the meaning of the error.

**DESCRIPTION:** After calling `beginTransaction`, all subsequent actions that modify the database are grouped within this transaction, known as the current transaction. Nested transactions are not supported. If `beginTransaction` is called when a transaction is already open, an error message will be returned.

**SEE:** [#link <sedbc>](#), [Database `commitTransaction\(\)`](#), [Database `rollbackTransaction\(\)`](#)

**EXAMPLE:**

```
var err = db.beginTransaction();
```

---

---

### Database `commitTransaction()`

---

**SYNTAX:** `database.commitTransaction()`

**RETURN:** number - 0 if the call was successful; otherwise, a nonzero status code based on the error message produced by the database. If the method returns a nonzero status code, use the `majorErrorCode` and `majorErrorMessage` methods to interpret the meaning of the error.

**DESCRIPTION:** This method commits all of the actions performed since the last call to `beginTransaction`. If there is no current transaction (for instance, the application has not called `beginTransaction`), calls to `commitTransaction` are ignored.

**SEE:** [#link <sedbc>](#), [Database `beginTransaction\(\)`](#), [Database `rollbackTransaction\(\)`](#)

**EXAMPLE:**

```
var err = db.commitTransaction();
```

---

---

### Database `connect()`

---

**SYNTAX:** `database.connect(dbtype, server, username, password)`

**WHERE:** `dbtype` - A string representing the database type. Currently only "ODBC" is supported.

`server` - Data source name. On Windows systems using ODBC, this is specified in the ODBC Administrator Control Panel; on UNIX, in the `.odbc.ini` file. See your database or system administrator for more information.

`username` - Name of the user to connect to the database. Some

---

---

relational database management systems (RDBMS) require that this be the same as your operating system login name; others maintain their own collections of valid user names. If in doubt, see your system administrator.

password - User's password. If the database does not require a password, use an empty string.

RETURN: number - 0 if the call was successful; otherwise, a nonzero status code based on the error message produced by the database. If the method returns a nonzero status code, use the `majorErrorCode` and `majorErrorMessage` methods to interpret the meaning of the error.

DESCRIPTION: Creates and caches a database connection to the specified database of the given type, using the username and password passed-in. When the connection goes out of scope, any pending transactions are rolled back. If any database connections are open when `connect` is called, they are closed and released before the new connection is opened.

SEE: [#link <sedbc>](#), [Database disconnect\(\)](#), [Database connected\(\)](#)

EXAMPLE: 

```
// This example creates a new database and
// then connects it to
// the database named "CLIENTS" using
// the username "ADMIN" and
// the password "admin-password"
var db = new database();
var err = db.connect("ODBC", "CLIENTS", "ADMIN",
                    "admin-passwd");
```

---

## Database connected()

---

SYNTAX: `database.connected()`

RETURN: boolean - `true` if the Database object is currently connected to a data source, `false` otherwise.

DESCRIPTION: This method returns `true` if the Database object is currently connected to a database. If `connected` returns `false`, reconnect the database before performing any further database actions, otherwise the actions will result in errors.

SEE: [#link <sedbc>](#), [Database connect\(\)](#), [Database disconnect\(\)](#)

EXAMPLE: 

```
// This example first checks to see
// if the database is
// connected to a data source. If not,
// it connects it to the
// database named "CLIENTS" using
// the username "ADMIN" and the
// password "admin-password"
if (!db.connected())
    err = db.connect( "ODBC", "CLIENTS",
                    "ADMIN", "admin-passwd" );
```

---

## Database cursor()

---

SYNTAX: `database.cursor(sqlstatement[, mode])`

---

---

WHERE:	<p><code>sqlstatement</code> - String containing a SQL SELECT statement supported by the database server.</p> <p><code>mode</code> - optional parameter indicating whether the cursor can be modified.</p>
RETURN:	<p>object - a new Cursor object, representing the results of the specified SQL statement.</p>
DESCRIPTION:	<p>This method creates a Cursor object that contains the rows returned by the specified SQL SELECT statement in the <code>sqlstatement</code> parameter. If the SELECT statement does not return any rows, the resulting Cursor object also has no rows.</p> <p>The optional <code>mode</code> parameter specifies how the Cursor object will access and modify records. The options for this field are:</p> <ul style="list-style-type: none"> <li><code>Database.snapshot</code> - uses <code>SQLExtendedFetch</code>, static cursor</li> <li><code>Database.dynaset</code> - uses <code>SQLExtendedFetch</code>, keyset driven cursor</li> <li><code>Database.forwardOnly</code> - uses <code>SQLFetch</code></li> <li><code>Database.dynamic</code> - uses <code>SQLExtendedFetch</code>, dynamic cursor</li> </ul> <p>If no value is specified in the <code>mode</code> parameter, the cursor is created <code>Database.snapshot</code>.</p> <p>If an updateable Cursor object is desired, the virtual table returned by the <code>sqlstatement</code> parameter must be updateable. For example, the SELECT statement passed as the <code>sqlstatement</code> parameter cannot contain a GROUP BY clause. In addition, the query usually must retrieve key values from a table. For more information on constructing updateable queries, consult your database vendor's documentation.</p>
SEE:	<p><a href="#">#link &lt;sedbc&gt;, Cursor object</a></p>
EXAMPLE:	<pre>// This example creates the updateable cursor 'custs' // and // returns the columns 'ID', 'CUST_NAME', // and 'CITY' from the // customer table: custs = db.cursor("select id, cust_name,                   city from customer",                   Database.dynaset);</pre>

---

### Database disconnect()

---

SYNTAX:	<code>database.disconnect()</code>
RETURN:	<p>number - 0 if the call was successful; otherwise, a nonzero status code based on the error message produced by the database. If the method returns a nonzero status code, use the <code>majorErrorCode</code> and <code>majorErrorMessage</code> methods to interpret the meaning of the error.</p>

---

---

DESCRIPTION:	Disconnects Database object from its data source.
SEE:	<a href="#">#link &lt;sedbc&gt;</a> , <a href="#">Database connect()</a> , <a href="#">Database connected()</a>
EXAMPLE:	<pre>// The example checks to see if // the Database object is // connected to a data source, and, // if so, disconnects it. if (db.connected())     err = db.disconnect();</pre>

---

## Database execute()

---

SYNTAX:	<code>database.execute(sqlstatement)</code>
WHERE:	<code>sqlstatement</code> - string representing the SQL statement to execute.
RETURN:	number - 0 if the call was successful; otherwise, a nonzero status code based on the error message produced by the database. If the method returns a nonzero status code, use the <code>majorErrorCode</code> and <code>majorErrorMessage</code> methods to interpret the meaning of the error.
DESCRIPTION:	<p>This method allows execution of any data definition language (DDL) or data manipulation language (DML) SQL statement supported by the database server that does not return a cursor (such as <code>CREATE</code>, <code>ALTER</code>, or <code>DROP</code>). Each database supports a standard core of DDL and DML statements. In addition, a database may support DDL and DML statements specific to that database vendor. Use <code>execute</code> to call any of those statements. However, a database vendor may provide functions that are not DDL or DML statements. Do not use <code>execute</code> to call those functions. For example, do not call the Oracle <code>describe</code> function or the Informix <code>load</code> function from the <code>execute</code> method.</p> <p>Although the <code>execute</code> method can be used to perform data modification (<code>INSERT</code>, <code>UPDATE</code>, or <code>DELETE</code> statements), it is recommended that Cursor objects be used instead to achieve the same functionality. Using the Cursor object for these sorts of actions allows better database-type independence and also allows the use of binary large object (BLOB) data.</p> <p>When using the <code>execute</code> method, the SQL statement must strictly conform to the syntax requirements of the database server. For example, some servers require each SQL statement be terminated with a semicolon. See the server documentation for more information. If a transaction has not been started with <code>beginTransaction</code>, the single statement is automatically immediately committed when <code>execute</code> is called.</p>
SEE:	<a href="#">#link &lt;sedbc&gt;</a> , <a href="#">Database cursor()</a> , <a href="#">Database beginTransaction()</a> , <a href="#">Database commitTransaction()</a> , <a href="#">Database rollbackTransaction()</a>
EXAMPLE:	<pre>// This example deletes all records from the database // whose ID is 'requestedID'. It is recommended,</pre>

---

---

```
// however, that the Cursor object be used
// to perform this action.
err = db.execute("delete from customer where
customer.ID = " + requestedID );
```

---

### **Database majorErrorCode()**

---

**SYNTAX:** `database.majorErrorCode()`

**RETURN:** variable - the result returned by this method varies depending on the database server being used, but contains an error code indicating why the most recent database activity failed.

**DESCRIPTION:** SQL statements can fail for a variety of reasons, including referential integrity constraints, lack of user privileges, record or table locking in a multiuser database, and so on. When an action fails, the database server returns an error code indicating the reason for failure. Use this method to fetch that error code.

**SEE:** [#link <sedbc>](#), [Database majorErrorMessage\(\)](#), [Database minorErrorCode\(\)](#), [Database minorErrorMessage\(\)](#)

**EXAMPLE:** `errCode = db.majorErrorCode();`

---

### **Database majorErrorMessage()**

---

**SYNTAX:** `database.majorErrorMessage()`

**RETURN:** variable - the result returned by this method varies depending on the database server being used, but contains an error message explaining why the most recent database activity failed.

**DESCRIPTION:** SQL statements can fail for a variety of reasons, including referential integrity constraints, lack of user privileges, record or table locking in a multiuser database, and so on. When an action fails, the database server returns an error message indicating the reason for failure. Use this method to fetch that error message.

**SEE:** [#link <sedbc>](#), [Database majorErrorCode\(\)](#), [Database minorErrorCode\(\)](#), [Database minorErrorMessage\(\)](#)

**EXAMPLE:** `errMessage = db.majorErrorMessage();`

---

### **Database minorErrorCode()**

---

**SYNTAX:** `database.minorErrorCode()`

**RETURN:** variable - the result returned by this method varies depending on the database server being used. In general, the method returns a secondary error code indicating a condition where the last database activity may not have completed as expected.

**DESCRIPTION:** The result returned by this method varies depending on the database server being used. In general, the method returns a secondary error code indicating a condition where the last database activity may not have completed as expected.

**SEE:** [#link <sedbc>](#), [Database majorErrorCode](#), [Database majorErrorMessage](#), [Database minorErrorMessage\(\)](#)

**EXAMPLE:** `errCode = db.minorErrorCode();`

---

## Database minorErrorMessage()

---

**SYNTAX:** `database.minorErrorMessage()`  
**RETURN:** variable - the result returned by this method varies depending on the database server being used. In general, the method returns a secondary error message indicating a condition where the last database activity may not have completed as expected.  
**DESCRIPTION:** This method returns the secondary error message returned by database vendor library.  
**SEE:** #link <sedbc>, [Database majorErrorCode](#), [Database majorErrorMessage](#), [Database minorErrorCode\(\)](#)  
**EXAMPLE:** `errCode = db.minorErrorMessage();`

---

## Database procedureName()

---

**SYNTAX:** `database.procedureName(n)`  
**WHERE:** n - Zero-based integer corresponding to the stored procedure in the database.  
**RETURN:** The name of the stored procedure with index n.  
**DESCRIPTION:** This method returns the name of the stored procedure corresponding to the specified index, n.  
**SEE:** #link <sedbc>, [Stproc object](#), [Database storedProc\(\)](#)  
**EXAMPLE:** `// fetch the name of stored procedure 0  
procName = db.procedureName(0);`

---

## Database procedures()

---

**SYNTAX:** `database.procedures()`  
**RETURN:** number - number of stored procedures in the database.  
**DESCRIPTION:** This method returns the number of procedures stored in the database.  
**SEE:** #link <sedbc>, [Stproc object](#), [Database storedProc\(\)](#), [Database procedureName\(\)](#)  
**EXAMPLE:** `// get the number of stored procedures in 'db'  
procCount = db.procedures();`

---

## Database rollbackTransaction()

---

**SYNTAX:** `database.rollbackTransaction()`  
**RETURN:** number - 0 if the call was successful; otherwise, a nonzero status code based on the error message produced by the database. If the method returns a nonzero status code, use the `majorErrorCode` and `majorErrorMessage` methods to interpret the meaning of the error.  
**DESCRIPTION:** This method undoes all actions performed since the last call to `beginTransaction`. If there is no current transaction (for instance, the application has not called `beginTransaction`),

---

---

calls to `rollbackTransaction` are ignored.

SEE: [#link <sedbc>, Database beginTransaction\(\), Database commitTransaction\(\)](#)

EXAMPLE: `err = db.rollbackTransaction()`

---

### Database storedProc()

---

SYNTAX: `database.storedProc(procName)`

WHERE: `procName` - String specifying the name of a stored procedure or SQL statements with parameters.

RETURN: object - new `Stproc` object.

DESCRIPTION: This method creates a stored procedure object (`Stproc`) from either the named stored procedure contained within the Database object, or from the passed-in SQL statement.

SEE: [#link <sedbc>, Stproc object, Database procedures\(\), Database procedureName\(\)](#)

EXAMPLE: 

```
// this example create a new database,
//and then executes
// a stored procedure contained within
var db = new Database;
db.connect(DBEngine, DataSource, User, Password);
var sp = db.storedProc("SomeProc");
sp.ItemID = 123;
sp.execute();

// now, execute an SQL Stproc
sp = db.storedProc("delete from Items where Weight =
?" );
sp[0] = 1000;
sp.execute();

// clean up
sp.close();
db.close();
```

---

### Database table()

---

SYNTAX: `database.table(tableName[,mode])`

WHERE: `tableName` - The name of an existing table in the database.

`mode` - optional parameter indicating whether the cursor can be modified.

RETURN: object - Cursor object representing the specified database table.

DESCRIPTION: This method creates a new `Cursor` object from the specified table stored in the database. The resulting `Cursor` has one row for each row in the database table and will be empty if the database table has no rows.

The optional `mode` parameter specifies how the `Cursor` object will access and modify records. The options for this field are:

`Database.snapshot` - uses `SQLExtendedFetch`, static

---

---

## cursor

Database.dynaset - uses SQLExtendedFetch, keyset driven cursor

Database.forwardOnly - uses SQLFetch

Database.dynamic - uses SQLExtendedFetch, dynamic cursor

If no value is specified in the mode parameter, the cursor is created Database.snapshot.

If an updateable Cursor object is desired, the virtual table returned by the sqlstatement parameter must be updateable. For example, the SELECT statement passed as the sqlstatement parameter cannot contain a GROUP BY clause. In addition, the query usually must retrieve key values from a table. For more information on constructing updateable queries, consult your database vendor's documentation.

SEE: #link <sedbc>, [Cursor object](#), [Database tables\(\)](#), [Database tableName\(\)](#)

EXAMPLE: 

```
// create a new Cursor object
// from the "clients" database table
clientsCurs = db.table( "clients", false );
```

---

## Database tableName()

---

SYNTAX: database.tableName(n)

WHERE: n - Zero-based integer corresponding to the table in the database.

RETURN: string - name of the table in the database with index n.

DESCRIPTION: This method returns the name of the database table corresponding to the specified index, n.

SEE: #link <sedbc>, [Database table\(\)](#), [Database tables\(\)](#)

EXAMPLE: 

```
// fetch the name of database table 0
tableName = db.tableName( 0 );
```

---

## Database tables()

---

SYNTAX: database.tables()

RETURN: number - number of tables in the database.

DESCRIPTION: This method returns the number of tables stored in the database.

SEE: #link <sedbc>, [Database table\(\)](#), [Database tableName\(\)](#)

EXAMPLE: 

```
// get the number of tables in 'db'
tableCount = db.tables();
```

---

## SimpleDataset object

```
title: SimpleDataset object
platform: Win32; all versions of SE
source: #include <smdtset.jsh>
```

A SimpleDataset object is an easy-to-use database-access object that combines database and cursor functionality into a single object.

SimpleDataset is a JavaScript class that combines the concept of a table and a cursor into a single, easy-to-use object. No more than one table may be represented by a SimpleDataset, so inserting items into the dataset doesn't require a target table to be specified. SQL is not needed to use a SimpleDataset and all operations can be performed through simple method calls.

When a SimpleDataset is created, it initially contains all of the rows ("records") in the specified table. The find() method allows this set to be reduced to only those records that match specified templates.

A SimpleDataset has the notion of the "current record". This is the record that SimpleDataset operations will affect. When the SimpleDataset is first created, the current record is the record "before" the first record, and is thus undefined.

Use the firstRecord(), lastRecord(), nextRecord(), and prevRecord() methods, to step through the records in the SimpleDataset. The current record is returned by currentRecord(). The objects returned by these routines have one property for each of the current record's fields.

The current record can be deleted using deleteRecord(). All items in the dataset can be deleted by deleteAll().

Records can be inserted into the table of the SimpleDataset by insertRecord(). The "current" record can be replaced by a specified record using replaceRecord().

A Cursor object representing the SimpleDataset can be obtained by using the cursor() method. It may be necessary to use this to perform more powerful operations on the dataset.

Although the SimpleDataset can be closed through its close() method, it is automatically closed when the object goes out of scope.

Using the SimpleDataset object, the following five-line script can be used to print out the contents of a database:

```
function print_all(db, table, user, passwd)
{
    var ds = new SimpleDataset(db, table, user, passwd);

    while(var rec = ds.nextRecord())
        for(var prop in rec)
            Screen.writeln(prop + " = " + rec[prop]);

    ds.close();
}
```

## SimpleDataset instance methods

### SimpleDataset()

---

SYNTAX:	new SimpleDataset(database, table, username, password)
WHERE:	database - The name of the ODBC database to open. On Windows systems using ODBC, this is specified in the ODBC Administrator Control Panel; on UNIX, in the .odbc.ini file. See

---

---

your database or system administrator for more information.

table - the name of the database table to use.

username - name of the user to connect to the database. Some relational database management systems (RDBMS) require that this be the same as your operating system login name; others maintain their own collections of valid user names. If in doubt, see your system administrator.

password - user's password. If the database does not require a password, use an empty string.

RETURN: object - a new `SimpleDataset`, or null on error.

DESCRIPTION: Constructor for the `SimpleDataset` object. When the `SimpleDataset` is created, it contains all of the elements in the table. The current element is set to the one "before" the first element in the dataset (and thus is "out of range").

SEE: `#include <smdtset.jsh>`

EXAMPLE: 

```
// create a SimpleDataset connected to the database
// named "corporate", table named "clients" using
// the username "ADMIN" and the password
// "admin-password"
var ds = new SimpleDataset("corporate", "clients",
                          "ADMIN", "admin-password");
```

---

### **SimpleDataset close()**

---

SYNTAX: `simpledataset.close()`

RETURN: boolean - value indicating success. In the case that the operation failed, use the `getLastErrorCode()` and `getLastErrorMessage()` methods to determine the reason for the failure.

DESCRIPTION: This method closes the `SimpleDataset` object, freeing up the system resources being used by it. It also closes the associated, hidden, database and `Cursor` objects.

SEE: `#include <smdtset.jsh>`

EXAMPLE: `var success = ds.close();`

---

### **SimpleDataset currentRecord()**

---

SYNTAX: `simpledataset.currentRecord()`

RETURN: object - the current record of a `SimpleDataset`, or null if the current record is out of range.

DESCRIPTION: This method returns the record for the current record in the `SimpleDataset`. If the current element is undefined, null is returned. The returned object has one property for each field of the current record a `SimpleDataset`.

SEE: `#include <smdtset.jsh>`, [SimpleDataset nextRecord\(\)](#), [SimpleDataset prevRecord\(\)](#), [SimpleDataset firstRecord\(\)](#), [SimpleDataset lastRecord\(\)](#)

EXAMPLE: `// get the current record`

---

---

```
var cr = ds.currentRecord();

// print out all of the fields of the object
for( var prop in cr )
    Clib.printf(prop + " = " + cr[prop] + "\n");
```

---

### **SimpleDataset nextRecord()**

---

**SYNTAX:** `simpledataset.nextRecord()`  
**RETURN:** object - the next record in the SimpleDataset. If there is no next record, null is returned.

**DESCRIPTION:** This method moves the current record forward in the SimpleDataset and returns the new current record. If the previous current record was the last record or the SimpleDataset is empty, null is returned.

**SEE:** `#include <smtdset.jsh>`, [SimpleDataset currentRecord\(\)](#), [SimpleDataset prevRecord\(\)](#), [SimpleDataset firstRecord\(\)](#), [SimpleDataset lastRecord\(\)](#)

**EXAMPLE:**

```
// get the next record
var rec = ds.nextRecord();

// so long as the record isn't null, print out all
// of the fields of the object
if( null != rec )
    for( var prop in rec )
        Clib.printf(prop + " = " + rec[prop] + "\n");
```

---

### **SimpleDataset prevRecord()**

---

**SYNTAX:** `simpledataset.prevRecord()`  
**RETURN:** object - the previous record in the SimpleDataset. If there is no previous record, null is returned.

**DESCRIPTION:** object - the previous record in the SimpleDataset. If there is no previous record, null is returned.

**SEE:** `#include <smtdset.jsh>`, [SimpleDataset currentRecord\(\)](#), [SimpleDataset nextRecord\(\)](#), [SimpleDataset firstRecord\(\)](#), [SimpleDataset lastRecord\(\)](#)

**EXAMPLE:**

```
// get the previous record
var rec = ds.prevRecord();

// so long as the record isn't null, print out all
// of the fields of the object
if( null != rec )
    for( var prop in rec )
        Clib.printf(prop + " = " + rec[prop] + "\n");
```

---

### **SimpleDataset firstRecord()**

---

**SYNTAX:** `simpledataset.firstRecord()`  
**RETURN:** object - the first record in the SimpleDataset. If the SimpleDataset is empty, null is returned.

**DESCRIPTION:** This method moves the current record to the first record in the

---

---

SimpleDataset and returns the new current record. If the SimpleDataset is empty, null is returned.

SEE: `#include <smdtset.jsh>`, [SimpleDataset currentRecord\(\)](#), [SimpleDataset nextRecord\(\)](#), [SimpleDataset prevRecord\(\)](#), [SimpleDataset lastRecord\(\)](#)

EXAMPLE: 

```
// get the first record
var rec = ds.firstRecord();

// so long as the record isn't null, print out all
// of the fields of the object
if( null != rec )
    for( var prop in rec )
        Clib.printf(prop + " = " + rec[prop] + "\n");
```

---

### **SimpleDataset lastRecord()**

---

SYNTAX: `simpledataset.lastRecord()`

RETURN: object - the last record in the SimpleDataset. If the SimpleDataset is empty, null is returned.

DESCRIPTION: This method moves the current record to the last record in the SimpleDataset and returns the new current record. If the SimpleDataset is empty, null is returned.

SEE: `#include <smdtset.jsh>`, [SimpleDataset currentRecord\(\)](#), [SimpleDataset nextRecord\(\)](#), [SimpleDataset prevRecord\(\)](#), [SimpleDataset firstRecord\(\)](#)

EXAMPLE: 

```
// get the last record
var rec = ds.lastRecord();

// so long as the record isn't null,
// print out all of the
// of the fields of the object
if( null != rec )
    for( var prop in rec )
        Clib.printf(prop + " = " + rec[prop] + "\n");
```

---

### **SimpleDataset find() with template**

---

SYNTAX: `simpledataset.find(template1[, template2[, ...]])`

WHERE: templateN - Item template to search for. When more than one template is present, the templates are OR'd together.

Templates contain properties to match. Only those records which have properties that match those values will be included in the result set.

RETURN: boolean - value indicating success. In the case that the operation failed, use the `getLastErrorCode()` and `getLastErrorMessage()` methods to determine the reason for the failure.

DESCRIPTION: This method searches the database table of a SimpleDataset for all items that match the given templates. The contents of the SimpleDataset are changed to reflect the results of the search. The previous contents of the SimpleDataset are cleared and the complete database table is searched to create the new

---

---

contents.

After the `find` has completed, the current record is set to the record "before" the first record. Fill out the properties in the template to indicate which items to find. For instance, to find all records whose 'city' field equals "Metropolis", set the value of the 'city' property to "Metropolis". If a template has more than one property, the properties will be combined with an AND to form the search term.

More than one template can be used. If multiple templates are used, the template values will be combined using an OR to form the search term.

SEE: [#include <smtdset.jsh>](#), [SimpleDataset findAll\(\)](#), [SimpleDataset findDistinct\(\)](#), [SimpleDataset caseSensitive](#)

EXAMPLE:

```
// the following function will print out the fields
// of each of the records that have either Boston,
// USA or Paris, France as
// their city, country values
function print_BostonParis(db, table, user, passwd)
{
    // create the SimpleDataset
    var ds = new SimpleDataset(db, table, user,
                               passwd);

    var template1, template2;

    template1.city = "Boston";
    template1.country = "USA";

    template2.city = "Paris";
    template2.country = "France";

    ds.find( template1, template2 );

    while( var rec = ds.nextRecord() )
        for( var prop in rec )
            Clib.printf(prop + " = " + rec[prop] +
                        "\n");

    ds.close();
}
```

---

### **SimpleDataset find() with clause**

---

SYNTAX: `simpledataset.find(whereClause)`

WHERE: `whereClause` - A string containing the `WHERE` clause of an SQL statement (without the word `WHERE`) indicating which items to find.

RETURN: Boolean value indicating success. In the case that the operation failed, use the `getLastErrorCode()` and `getLastError()` methods to determine the reason for the failure.

DESCRIPTION: This method searches the database table of a `SimpleDataset` for all items that match the given SQL `WHERE` clause. The contents of the `SimpleDataset` are changed to reflect the results of the

---

---

search. The previous contents of the `SimpleDataset` are cleared and the complete database table is searched to create the new contents.

After the `find` has completed, the current record is set to the record "before" the first record.

The string passed into `find` contains a SQL `WHERE` clause. This allows more elaborate searches to be performed.

SEE: `#include <smtdtset.jsh>`, [SimpleDataset findAll\(\)](#), [SimpleDataset findDistinct\(\)](#)

EXAMPLE:

```
// the following function will print out the fields
// of each of the records that have either Boston
// or Paris as their city values
function print_BostonParis(db, table, user, passwd)
{
    // create the SimpleDataset
    var ds = new SimpleDataset(db, table, user,
                               passwd);

    var whereClause;

    whereClause = "(City = \'Boston\') OR
                  (City = \'Paris\')";

    ds.find(template1, template2);

    while(var rec = ds.nextRecord())
        for(var prop in rec)
            Clib.printf(prop + " = " + rec[prop] +
                        "\n");

    ds.close();
}
```

---

### **SimpleDataset findAll()**

SYNTAX: `simpledataset.findAll()`

RETURN: boolean - value indicating success. In the case that the operation failed, use the `getLastErrorCode()` and `getLastErrorMessage()` methods to determine the reason for the failure.

DESCRIPTION: This method clears the contents of the `SimpleDataset` and replaces them with the entire contents of the database table. Effectively, this resets the `SimpleDataset` to its initial state.

After setting the new contents, the current record is set to the record "before" the first record.

SEE: `#include <smtdtset.jsh>`, [SimpleDataset find\(\) with template](#), [SimpleDataset find\(\) with clause](#), [SimpleDataset findDistinct\(\)](#)

EXAMPLE:

```
// reset the contents of the SimpleDataset
err = ds.findAll();
```

---

### **SimpleDataset findDistinct()**

---

SYNTAX:	<code>simpledataset.findDistinct(field)</code>
WHERE:	field - string indicating for which field duplicate values should be filtered out.
RETURN:	boolean - value indicating success. In the case that the operation failed, use the <code>getLastErrorCode()</code> and <code>getLastError()</code> methods to determine the reason for the failure.
DESCRIPTION:	This method removes all records from the <code>SimpleDataset</code> that have duplicate values for the indicated fields. In other words, for the given field, only one record with each value is left in the <code>SimpleDataset</code> .  Note that no guarantees are made as to which records are left in the <code>SimpleDataset</code> for each value of the field.
SEE:	<code>#include &lt;smdtset.jsh&gt;</code> , <a href="#">SimpleDataset find()</a> with template, <a href="#">SimpleDataset find()</a> with clause, <a href="#">SimpleDataset findAll()</a>
EXAMPLE:	<pre>// print the unique country values // in a SimpleDataset function unique_countries(db, table, user, passwd) {     var ds = new SimpleDataset(db, table, user,                                passwd );      // find the distinct country values     ds.findDistinct( "country" );      while( var rec = ds.nextRecord() )         Clib.printf(var.country + "\n"); } </pre>

---

### **SimpleDataset addRecord()**

---

SYNTAX:	<code>simpledataset.addRecord(record)</code>
WHERE:	record - Object whose properties contain the values of the fields of the record to be added to the database table.
RETURN:	boolean - value indicating success. In the case that the operation failed, use the <code>getLastErrorCode()</code> and <code>getLastError()</code> methods to determine the reason for the failure.
DESCRIPTION:	This method inserts the specified record into the <code>SimpleDataset</code> and its associated database table. The record to be inserted will have the field values indicated by the properties of the object passed into <code>addRecord</code> . After inserting a new record, the current record is left unchanged.  Note that no guarantees are made about the position of the inserted record within the <code>SimpleDataset</code> .
SEE:	<code>#include &lt;smdtset.jsh&gt;</code> , <a href="#">SimpleDataset deleteRecord()</a> , <a href="#">SimpleDataset deleteAll()</a>
EXAMPLE:	<pre>// The following function opens a SimpleDataset, // adds the city // Boston, Massachusetts to it, </pre>

---

---

```

// and then closes it down
function add_city(db, table, user, passwd)
{
    var ds = new SimpleDataset(db, table, user,
                               passwd );

    // set up the field values
    // of the item to be added
    var record;
    record.city = "Boston";
    record.country = "USA";
    record.state = "Massachusetts";
    record.population = 500000;

    // add the item and clean up
    ds.addRecord( record );
    ds.close();
}

```

---

### **SimpleDataset deleteRecord()**

---

**SYNTAX:** `simpledataset.deleteRecord()`  
**RETURN:** `boolean` - value indicating success. In the case that the operation failed, use the `getLastErrorCode()` and `getLastErrorMessage()` methods to determine the reason for the failure.

**DESCRIPTION:** This method removes the current record from the `SimpleDataset` and its associated database table. After deleting the record, the current record is set to the record "before" the first record.

**SEE:** `#include <smdtset.jsh>`, [SimpleDataset deleteAll\(\)](#)

**EXAMPLE:**

```

// This function will delete all records
// with USA as their country
function delete_USA(db, table, user, passwd)
{
    var ds = new SimpleDataset(db, table, user,
                               passwd );

    // find the entries whose country is USA
    var template;
    template.country = "USA";
    ds.find( template );

    // delete the records from the SimpleDataset
    // and clean up
    while( ds.next() )
        ds.deleteRecord();
    ds.close();
}

```

---

### **SimpleDataset deleteAll()**

---

**SYNTAX:** `simpledataset.deleteAll()`  
**RETURN:** `boolean` - value indicating success. In the case that the operation failed, use the `getLastErrorCode()` and `getLastErrorMessage()` methods to determine the reason for the failure.

**DESCRIPTION:** This method removes all records from the `SimpleDataset`. The corresponding rows will also be deleted from the associated

---

---

database table.

SEE: `#include <smdtset.jsh>`, [SimpleDataset deleteRecord\(\)](#)

EXAMPLE:

```
// This function will delete all records
// with USA as their country
function delete_USA(db, table, user, passwd)
{
    var ds = new SimpleDataset(db, table, user,
                               passwd );

    // find the entries whose country is USA
    var template;
    template.country = "USA";
    ds.find(template);

    // delete the records from the SimpleDataset
    // and clean up
    ds.deleteAll();
    ds.close();
}
```

---

### **SimpleDataset replaceRecord()**

---

SYNTAX: `simpledataset.replaceRecord(record)`

WHERE: `record` - object whose properties contain the values of the fields of the record to replace the current record with.

RETURN: `boolean` - value indicating success. In the case that the operation failed, use the `getLastErrorCode()` and `getLastErrorMessage()` methods to determine the reason for the failure.

DESCRIPTION: This method replaces the current record in the `SimpleDataset` with the specified record. The record that the current record will be replaced with will have the field values indicated by the properties of the object passed into `addRecord`. After inserting a new record, the current record remains unchanged; that is, the current record is the record that replaced the previous current record.

SEE: `#include <smdtset.jsh>`, [SimpleDataset addRecord\(\)](#), [SimpleDataset deleteRecord\(\)](#)

EXAMPLE:

```
// This function will set the population
// of the first record
// with USA as its country to 100,000
function replace_population(db, table, user,
                           passwd)
{
    var ds = new SimpleDataset(db, table, user,
                               passwd );

    // find the entries whose country is USA
    var template;
    template.country = "USA";
    ds.find(template);

    // advance to first record in the result set
    var rec = ds.nextRecord();

    if( null != rec )
```

---

---

```

    {
        // set the new population value
        rec.population = 100000;

        // replace the record and clean up
        ds.replaceRecord(rec);
    }
    ds.close();
}

```

---

### SimpleDataset cursor()

**SYNTAX:** `simpledataset.cursor()`

**RETURN:** object - the `Cursor` object that represents the current contents of the `SimpleDataset`

**DESCRIPTION:** This method returns the `Cursor` object that represents the `SimpleDataset`. This may be useful if functionality beyond that of the `SimpleDataset` is required.

**SEE:** `#include <smdtset.jsh>`, [Cursor object](#)

**EXAMPLE:** `// get the SimpleDataset as a Cursor`  
`var curs = ds.cursor();`

---

### SimpleDataset getLastErrorCode()

**SYNTAX:** `simpledataset.getLastErrorCode()`

**RETURN:** number - integer specifying error code

**DESCRIPTION:** This method returns an integer containing the code of any error encountered by the last `SimpleDataset` method call. The error codes/strings are reset whenever a `SimpleDataset` method is called (excluding `getLastErrorCode()` and `getLastError()`).

**SEE:** `#include <smdtset.jsh>`, [SimpleDataset getLastError\(\)](#)

**EXAMPLE:** `// get the error code`  
`errCode = ds.getLastErrorCode();`

---

### SimpleDataset getLastError()

**SYNTAX:** `simpledataset.getLastError()`

**RETURN:** string - message describing the last error encountered.

**DESCRIPTION:** This method returns a string explaining the error encountered by the last `SimpleDataset` method call. The error codes/strings are reset whenever a `SimpleDataset` method is called (excluding `getLastErrorCode()` and `getLastError()`).

**SEE:** `#include <smdtset.jsh>`, [SimpleDataset getLastErrorCode\(\)](#)

**EXAMPLE:** `// get a string describing the error`  
`error = ds.getLastError();`

---

## SimpleDataset static properties

### SimpleDataset.caseSensitive

---

SYNTAX:	<code>SimpleDataset.caseSensitive</code>
DESCRIPTION:	Boolean value indicating whether or not <code>find</code> calls are case sensitive. By default, searches are not case sensitive.
SEE:	<code>#include &lt;smtdset.jsh&gt;</code> , <a href="#">SimpleDataset find() with template</a> , <a href="#">SimpleDataset find() with clause</a>
EXAMPLE:	<pre>// turn on case sensitivity // for SimpleDataset searches ds.caseSensitive = true;</pre>

---

## Stproc object

```
title: Stproc Object
platform: Win32; all versions of SE
source: #link <sedbc>
```

An Stproc object represents a call to a database stored procedure or SQL statement with parameters.

The Stproc object represents a stored procedure. A stored procedure is an SQL statement or other procedure that can be saved in a database object. The procedure object can be recalled and executed, if necessary returning its results as a Cursor object.

## Stproc instance properties

The properties of Stproc objects vary from instance to instance. Each Stproc object has a property for each parameter in the stored procedure or SQL statement. Thus, when an Stproc object is created, it acquires a property for each of its parameters.

Parameters of an Stproc object may also be referred to as elements of an array. The 0-index array element corresponds to the first parameter, the 1-index array element corresponds to the second parameter, and so forth.

The following example demonstrates how to call a stored procedure using named parameter properties. A `GetCityArea` procedure might be defined in a MS Access database as follows:

```
/*
PARAMETERS AreaParam Text, CityParam Text;
SELECT Table3.* FROM Table3
WHERE ((Table3.Area=[AreaParam]) AND
      (Table3.City=[CityParam]));
*/

// Recall the Stproc object 'GetCityArea' from the database
sp = db.storedProc("GetCityArea");

// Set the parameter values
sp.AreaParam = "Europe";
sp.CityParam = "Paris";

// Execute the stored procedure
citySet = sp.cursor();

// Clean up
citySet.close();
sp.close();
```

```

/*
   This example uses the same procedure, but accesses the
   parameters through array indexes.
*/

// Recall the Stproc object 'GetCityArea' from the database
sp = database.storedProc("GetCityArea");

// Set the parameter values
sp[0] = "Europe";
sp[1] = "Paris";

// Execute the stored procedure
citySet = sp.cursor();

// Clean up
citySet.close();
sp.close();

```

## Stproc instance methods

### Stproc close()

---

**SYNTAX:** `stproc.close()`

**RETURN:** number - 0 if the call was successful; otherwise, a nonzero status code based on the error message produced by the database. If the method returns a nonzero status code, use the associated Database's `majorErrorCode` and `majorErrorMessage` methods to interpret the meaning of the error.

**DESCRIPTION:** This method closes an `Stproc` object and releases the memory it uses. If an `Stproc` object is not explicitly closed with the `close` method, the runtime engine automatically it when the corresponding database object goes out of scope.

**SEE:** [#link <sedbc>, Database majorErrorCode\(\), Database minorErrorCode\(\)](#)

**EXAMPLE:** `// Close down the Stproc  
err = sp.close();`

---

### Stproc parameterName()

---

**SYNTAX:** `stproc.parameterName(n)`

**WHERE:** `n` - zero-based integer corresponding to the parameter in the `Stproc` object. The first parameter is 0, the second is 1, etc.  
return:

**RETURN:** string - the name of parameter `n`.

**DESCRIPTION:** This method returns the name of the parameter corresponding to the given index.

**SEE:** [#link <sedbc>, Stproc parameters\(\)](#)

**EXAMPLE:** `// fetch the second parameter name  
// of the Stproc 'sp'  
paramName = sp.parameterName( 1 );`

---

## Stproc parameters()

---

**SYNTAX:** `stproc.parameters()`  
**RETURN:** number - parameters in the Stproc.

**DESCRIPTION:** This method returns the number of named and unnamed parameters for the stored procedure or SQL statement.

**SEE:** #link <sedbc>, [Stproc parameterName\(\)](#)

**EXAMPLE:**

```
// create an array of parameter names
// for Stproc 'sp'
for( i=0; i<sp.parameters(); i++ )
    pNames[i] = sp.parameterName( i );
```

---

## Stproc cursor()

---

**SYNTAX:** `stproc.cursor([updateable])`  
**WHERE:** updateable - Boolean parameter indicating whether the cursor can be modified.

**RETURN:** A new Cursor object, representing the results of the stored procedure.

**DESCRIPTION:** This method creates a Cursor object that contains the rows returned by the SQL `SELECT` statement of the stored procedure object. If the `SELECT` statement does not return any rows, the resulting Cursor object also has no rows.

The optional `mode` parameter specifies how the Cursor object will access and modify records. The options for this field are:

- `Database.snapshot` - uses `SQLExtendedFetch`, static cursor
- `Database.dynaset` - uses `SQLExtendedFetch`, keyset driven cursor
- `Database.forwardOnly` - uses `SQLFetch`
- `Database.dynamic` - uses `SQLExtendedFetch`, dynamic cursor

If no value is specified in the `mode` parameter, the cursor is created `Database.snapshot`.

If an updateable Cursor object is desired, the virtual table generated by the stored procedure must be updateable. For example, the `SELECT` statement cannot contain a `GROUP BY` clause. In addition, the query usually must retrieve key values from a table. For more information on constructing updateable queries, consult your database vendor's documentation.

**SEE:** #link <sedbc>, [Cursor object](#), [Stproc execute\(\)](#)

**EXAMPLE:**

```
// create a SQL stored procedure
SQL = "select id, cust_name, city from customer"
      "where (id >=?) and (id <=?)" ;
sp = database.storedProc(SQL);

// set the parameters
```

---

---

```
sp[0] = 1000;
sp[1] = 2000;

// create the cursor
custs = sp.cursor(true)
```

---

## **Stproc execute()**

---

**SYNTAX:** `stproc.execute()`  
**RETURN:** number - 0 if the call was successful; otherwise, a nonzero status code based on the error message produced by the database. If the method returns a nonzero status code, use the associated Database's `majorErrorCode` and `majorErrorMessage` methods to interpret the meaning of the error.

**DESCRIPTION:** This method executes the stored procedure of SQL statement. It allows execution of any stored procedure or SQL statement that uses data definition language (DDL) or data manipulation language (DML) statements supported by the database server and that do not return a cursor (such as `CREATE`, `ALTER`, or `DROP`).

Each database supports a standard core of DDL and DML statements. In addition, a database may support DDL and DML statements specific to that database vendor. Use `execute` to call any of those statements. However, a database vendor may provide functions that are not DDL or DML statements. Do not use `execute` to call a stored procedure using those functions. For example, do not call the Oracle `describe` function or the Informix `load` function from a stored procedure's `execute` method. Although the `execute` method can be used to perform data modification (`INSERT`, `UPDATE`, or `DELETE` statements), it is recommended that `Cursor` objects be used instead to achieve the same functionality. Using the `Cursor` object for these sorts of actions allows better database-type independence and also allows the use of binary large object (BLOB) data.

When using the `execute` method, the stored procedure's SQL statement must strictly conform to the syntax requirements of the database server. For example, some servers require each SQL statement be terminated with a semicolon. See the server documentation for more information. If a transaction has not been started with `beginTransaction`, the single statement is automatically immediately committed when the stored procedure's `execute` method is called.

**SEE:** [#link <sedbc>, Stproc cursor\(\), Database majorErrorCode\(\), Database majorErrorMessage\(\)](#)

**EXAMPLE:**

```
// Create a new database object, and
// connect it to a data source
var a = new Database;
a.connect(DBEngine, DataSource, User, Password);

// execute the stored procedure 'SomeProc'
```

---

---

```
var sp = a.storedProc("SomeProc");
sp.ItemID = 123;
sp.execute();

// execute an SQL stored procedure
sp = a.storedProc("delete from Items where Weight =
?");
sp[0] = 1000;
sp.execute();

// clean up
sp.close();
a.close();
```

---

---

# Socket Link Library

The Socket object is used to communicate between computers over the internet through sockets.

## Socket object

platform: All OS except DOS and OS2; All Versions of SE  
source: #link <sesock>

## Socket object instance methods

---

### Socket() with hostname

---

**SYNTAX:** Socket(hostname, port)  
**WHERE:** hostname - Name of remote host to connect to  
port - Port of remote host to connect to  
**RETURN:** object - A new Socket object, or null on error  
**DESCRIPTION:** This method attempts to connect to the specified remote host. If the library is unable to connect to the remote host, then null is returned and error is set. Once the connection is established, the socket can be read from / written to until it is closed or the connection is lost.  
**SEE:** #link <sesock>, [Socket error\(\)](#)  
**EXAMPLE:**

```
function connect( hostnamePort )
{
    var index;
    var port = 1000; // Default port

    if( (index = hostnamePort.indexOf(":")) != -1 )
    {
        port = ToNumber(hostnamePort.substring(index,
            hostnamePort.length));
        hostnamePort = hostnamePort.substring(0,index);
    }

    var socket = Socket(hostnamePort, port);

    return socket;
}
```

---

---

### Socket() with port

---

**SYNTAX:** Socket(port)  
**WHERE:** port - Port to listen on  
**RETURN:** object - A Socket object, or null on error.  
**DESCRIPTION:** There are two types of sockets, in general. One type is a socket which is an established connection between a client and a server. This socket can be read to and written from just like a file. The other type of socket is a listening socket, which is a server-side socket which is not connected to a specific client, but rather to a certain port. It is listening for any new requests on that port.

---

---

Requests can be checked for using the `Socket.select()` method. Once it is established that there is a request waiting, the peer-to-peer connection can be established using the `accept()` method. This creates a new connection socket on another port, leaving the original socket still listening for incoming connections.

SEE: `#link <sesock>`, [Socket select\(\)](#), [Socket accept\(\)](#)

EXAMPLE:

```
var listenSocket = Socket( 1000 );

if( listenSocket != null )
{
    if( listenSocket.ready() )
    {
        var connectSocket = listenSocket.accept();
        if( connectSocket != null )
        {
            // Finally! we have the socket
            // ... do stuff with socket ...
            connectSocket.close();
        }
    }
}

/* Creates a socket to listen on port 1000
 * and wait for any incoming
 * connections. The no-parameter form
 * of ready() uses an infinite
 * timeout, so the program waits indefinitely
 * for a connection. This is
 * also equivalent to
 * "Socket.select(-1,listenSocket)", which is a
 * generic form which allows for
 * listening on multiple sockets.
 */
```

---

### **Socket accept()**

---

SYNTAX: `socket.accept()`

RETURN: `object` - A new socket object connected to the client of the incoming request, or `null` if there is an error.

DESCRIPTION: If there is no incoming request waiting on the socket, or this socket is not listening on a certain port, then it is an error and `null` is returned. Otherwise, the method establishes a socket connection on another port and returns a socket object representing this connection. The returned socket can later be used for reading/writing and other communication between the client and server.

SEE: `#link <sesock>`, [Socket select\(\)](#), [Socket ready\(\)](#)

---

### **Socket blocking()**

---

SYNTAX: `socket.blocking(flag)`

WHERE: `flag` - A boolean value indicating whether this socket is to be blocking or non-blocking.

---

---

RETURN: boolean - Whether the operation was successful.

DESCRIPTION: This method sets the state of the socket to be blocking if `flag` is `true`, and non-blocking otherwise. A blocking socket will wait indefinitely for data on reads, while a non-blocking socket will immediately exit with an error indicating that there is no data to be read. By default, all sockets are blocking when they are created.

SEE: `#link <sesock>`, [Socket select\(\)](#), [Socket read\(\)](#)

---

### Socket close()

---

SYNTAX: `socket.close()`

RETURN: boolean - Whether the operation was successful or not

DESCRIPTION: This method closes the specified socket and frees up any memory associated with the object. It must be called to appropriately dispose of the socket. If not explicitly called, then the socket will be automatically closed when the library is unloaded. If the socket is successfully closed, then `true` is returned, otherwise `false`. The nature of the error can be retrieved with [Socket error\(\)](#).

SEE: `#link <sesock>`, [Socket error\(\)](#)

---

### Socket linger()

---

SYNTAX: `socket.linger(flag[, timeout])`

WHERE: `flag` - A boolean value indicating whether this socket will linger or not

`timeout` - A timeout, in seconds, to wait for when closing the socket, only used when `linger` is on. This defaults to 10 if not supplied.

RETURN: boolean - Whether the operation was successful

DESCRIPTION: If `flag` is `true`, then this socket is set to linger, otherwise it is not. A lingering socket will remain active after closing it if there remains data to be read or written. If `linger` is not set, then the socket will immediately close, but any remaining data will be sent, if possible, before closing the socket. If `linger` is active, and `timeout` 0, then the socket is immediately closed and any unsent data is lost, simulating a hard close. Otherwise, the socket remains open until the data is transferred or `timeout` is reached. By default, all sockets are non-linging.

SEE: `#link <sesock>`, [Socket close\(\)](#)

---

### Socket read()

---

SYNTAX: `socket.read(destination, description)`

WHERE: `destination` - A destination variable which will be converted to

---

---

the appropriate type based on description.

description - A variable description, either one of the special Blob variables UWORD8, SWORD8, UWORD16, SWORD16, UWORD24, SWORD24, UWORD32, SWORD32, FLOAT32, FLOAT64, FLOAT80, a blobDescriptor object describing a structure, or a positive value indicating the length of a buffer to read.

RETURN: number - elements read.

DESCRIPTION: This method is almost identical to `Clib.fread()`, except that it reads from the current socket rather than a supplied file. The description variable acts in the same way as `Clib.fread()`. If it is a positive value, then destination is treated as a buffer and filled with raw data. Otherwise, one of the blob types or blob descriptors can be used to read data values. For buffers, the length of the buffer read is returned. For all other values, 1 is returned if the item is read successfully, -1 or 0 otherwise. Use `Socket error()` to determine the nature of the error. Typically, -1 means the socket is non-blocking and no data is available to read. 0 usually indicates that the program at the other end of the socket closed it.

SEE: #link <sesock>, `Clib.fread()`, `Socket write()`, `Socket error()`

EXAMPLE:

```
function readInfo( socket )
{
    var description = new blobDescriptor();
    description.name = 12;
    description.age = UWORD8;
    description.extension = UWORD16;
    var info;

    if( !socket.read( info, description ) )
        return null;
    else
        return info;
}

/* The above function will read the special
 * info data structure from
 * the socket, returning null
 * if there is some sort of error.
 */
```

---

## Socket ready()

SYNTAX: `socket.ready([timeout])`

WHERE: timeout - Maximum time to poll, in milliseconds, or -1 for no timeout

RETURN: boolean - whether the socket is ready for reading in the specified time.

DESCRIPTION: This method is very similar to `Socket.select()`, except that it only polls the current socket for input. If no timeout is specified or it is -1, then the socket is polled indefinitely, unless there is an error. This method is useful for simple applications, when there

---

---

are just a few sockets open, or in special instances where the `Socket.select()` method is impractical or impossible.

SEE: #link <sesock>, [Socket select\(\)](#)

EXAMPLE:

```
var listenSocket = Socket( 1000 );

// Assume 'done' is a global flag
if( listenSocket != null )
{
    while( !done )
    {
        if( listenSocket.ready(10) )
        {
            // Open connection with accept() ...
        }

        // Do other idle stuff...
    }

    listenSocket.close();
}

/* This code creates a socket listening
 * on port 1000, and continuously
 * polls it to see if there is
 * an incoming connection, alternatively doing
 * idle code when there is no connection ready.
 */
```

---

### Socket remoteHost()

---

SYNTAX: `socket.remoteHost()`

RETURN: string - The host this socket is connected to, or null if it is not connected.

DESCRIPTION: For listening sockets that are only connected to a port, then this method returns null. Otherwise, it returns the name of the remote host, either the server that the socket connected to, or the client from an incoming request. This method can be used to tell whether or not a socket is listening or is connected.

SEE: #link <sesock>

EXAMPLE:

```
var listenSocket = Socket( 1000 );

if( listenSocket != null )
{
    if( listenSocket.ready() )
    {
        var connection = listenSocket.accept();
        if( connection != null )
        {
            // Print out name of incoming request
            Screen.writeln( connection.remoteHost() );
            // .. do other stuff ...
            connection.close();
        }
    }
    listenSocket.close();
}
```

---

---

## Socket write()

---

**SYNTAX:** `socket.write(source, description)`  
**WHERE:** `source` - Source variable to write to the socket  
`description` - Variable description describing how to write the source variable to the socket.

**RETURN:** `number` - the number of elements written.

**DESCRIPTION:** This method is almost identical to `Clib.fwrite()`, except that it writes to the current socket, rather than to a supplied file. The `description` variable acts in the same way as in `Clib.fwrite()`. If it is a positive value, then `source` is treated as a buffer of the specified length. Otherwise, `description` must be a Blob value (SWORD8, UWORD32, etc) or a blobDescriptor object describing how the data should be written to the socket. If `source` is a buffer, then the number of bytes written is returned, otherwise 1 is returned if the datum is successfully written, -1 otherwise. Use `Socket error()` to determine the nature of the error.

**SEE:** `#link <sesock>`, `Clib.fwrite()`, `Socket read()`, `Socket error()`

**EXAMPLE:**

```
function writeInfo( socket, info )
{
    if( !socket.write( info.name, 12 ) ||
        !socket.write( info.age, UWORD8 ) ||
        !socket.write( info.extension, UWORD16 ) )
        return false;
    else
        return true;
}

/* This function will write the contents
 * of the info object to the
 * specified socket in a native data format.
 */
```

---

## Socket object static methods

---

### Socket.addressByName()

---

**SYNTAX:** `Socket.addressByName( address )`  
**WHERE:** `address` - Address of host to look up

**RETURN:** `string` - The address of the specified host.

**DESCRIPTION:** This method attempts to find the address of the specified host through a reverse DNS lookup. If this lookup is successful, then the address is returned as a string. Otherwise, `null` is returned.

**SEE:** `#link <sesock>`, `Socket.hostByName()`

---

---

### Socket.error()

---

**SYNTAX:** `Socket.error()`  
**RETURN:** `number` - The last error from the socket library

**DESCRIPTION:** When there is some sort of error within the socket library, the

---

---

special errno value gets set indicating the error number. If a method returns a value indicating an error, this method can be used to determine the exact nature of the error. The actual meaning of the value depends what system is being run.

SEE: #link <sesock>

---

### **Socket.hostByName()**

---

SYNTAX: `Socket.hostByName(name)`

WHERE: name - Name of host to look up

RETURN: string - The name of the specified host

DESCRIPTION: This method looks up the specified host through a DNS lookup and returns it. This method can be used to convert between numerical addresses and domain names, as well as resolving local names appropriately. If unable to find the host name, then null is returned.

SEE: #link <sesock>, [Socket.addressByName\(\)](#)

EXAMPLE: `var hostname = Socket.hostByName("44.55.66.77");`

---

### **Socket.hostName()**

---

SYNTAX: `Socket.hostName()`

RETURN: string - The name of the host

DESCRIPTION: This method attempts to find the name of the local host. If the call is successful, then a string is returned with the name of the host. Otherwise, the empty string is returned.

SEE: #link <sesock>

---

### **Socket.select()**

---

SYNTAX: `Socket.select([timeout,] socket1[, socket2  
...])`

WHERE: timeout - Maximum time to poll, in milliseconds, -1 for no timeout

socketN - A list of sockets to poll for data, or an array of sockets

RETURN: object - The first supplied socket object which is ready for reading, or null if none is ready before the timeout is reached.

DESCRIPTION: This method is an alternative to [Socket ready\(\)](#). The other ready method is a property of Socket instances, and only polls the current socket for data. This global method allows for polling of multiple sources, which is needed when multiple sockets are open. When any of the specified sockets are ready to be read from, then this method returns the first socket which is so ready. Note that these sockets can be either connected sockets or listening sockets. A listening socket that is ready to be read from means that a request is waiting. If no timeout is specified, then -1 (infinite) timeout is used.

---

---

SEE: #link <sesock>, [Socket ready\(\)](#)

EXAMPLE:

```
var listenSocket1 = Socket( 1000 );
var listenSocket2 = Socket( 1001 );

// Assume 'done' is a global flag somewhere
if( listenSocket1 != null && listenSocket2 != null )
{
    while( !done )
    {
        var acceptSocket;
        if((acceptSocket = Socket.select(100,
            [listenSocket1, listenSocket2])) != null)
        {
            // Connect with socket ...
        }

        // Do other stuff ...
    }
}

/* This code opens two sockets for listening,
 * and then continuously polls
 * these two sockets for incoming connections.
 * Note that in a real
 * program, it would be better to create
 * a dynamic array which holds all
 * of the open sockets.
 */
```

---

---

# UUCode Link Library

The Unix-To-Unix encoding library provides two functions for encoding and decoding data in a text format.

platform: Mac, OS2, Windows; All versions of SE  
source: #link <uucode>

## UU object static methods

### UU.encode()

---

**SYNTAX:** UU.encode(infile[, outfile])  
**WHERE:** infile - Name of input file  
outfile - Name of output file  
**RETURN:** boolean - Whether or not the operation was successful  
**DESCRIPTION:** This method uses the Unix-to-Unix encoding mechanism, still popular in newsgroups, as a way of translating binary data into printable text data. If `outfile` is not supplied, then an appropriate filename is generated by either adding or replacing the extension with ".uue". The file "foo.c" would become "foo.uue". This file later can be decoded with any popular UUdecoding program, or a call to UU.decode();  
**SEE:** #link <uucode>, [UU.decode\(\)](#)

---

### UU.decode()

---

**SYNTAX:** UU.decode(infile[, outfile])  
**WHERE:** infile - Name of input file  
outfile - Name of output file  
**RETURN:** boolean - Whether or not the operation was successful  
**DESCRIPTION:** This method decodes a file stored using the Unix-to-Unix encoding mechanism. If `outfile` is not supplied, then the filename that is stored in the infile (the original name of the file) is used instead.  
**SEE:** #link <uucode>, [UU.encode\(\)](#)

---

# Productivity Tools

ScriptEase ISDK 5.0 provides tools to increase your productivity and make the toolkit easier to use and integrate into your applications.

---

## ScriptEase ISDK Toolbox

The ScriptEase ISDK Toolbox is your launching pad when you work with ScriptEase ISDK. You can use it get started with ScriptEase as well as accessing Help, sample files, technical support, and other ISDK support tools. It has six main views:

- **Home.** General information and latest news about ScriptEase ISDK.
- **Getting Started.** Quick integration guide to getting you started with ScriptEase ISDK.
- **ISDK Help.** Your source for all online documentation included with ISDK.
- **Support.** Access our technical support web site directly from within the Toolbox application.
- **Samples.** Get a listing and descriptions of our sample projects.
- **Productivity Tools.** Launch our supporting productivity tools from within this view.

---

## Selib Assistant

Selib Assistant is a visual tool to simplify the .lib building process of ScriptEase ISDK. Selib Assistant provides a visual 2-way means of working with the Jseopt.h file rather than dealing with the underlying source. It works directly with the actual header file, so that you can work interchangeably with the Selib Assistant or the source file itself.

Selib Assistant also automates the process of building the ScriptEase core and library .lib files using Microsoft Visual Studio and adding them to your own Visual Studio projects.

**Note:** You must have Microsoft Visual Studio 6.0 installed on your system and in your path to use the Build and Add To Project features of Selib Assistant. If Selib Assistant does not find Visual Studio on your system, it will hide these features.

## Description of Selib Assistant Modes

There are three main modes of Selib Assistant:

**Set Options.** Provides two views for working with the `jseopt.h` file to declare compiler options.

**Build Libraries.** Builds core and extended library `.lib` files based on the current options set in the `jseopt.h` file.

**Add To Project.** Adds the built `.lib` files to a Microsoft Visual Studio project you specify.

## Set Options Mode

The `jseopt.h` file contains literally hundreds of compiler options that you can turn off/on depending on the specific needs of your application. Set Options mode is used to configure this file. You can work with the underlying `jseopt.h` file in two ways – Explorer View or Source View.

Both views are kept in synch such that when you check/uncheck an option in Explorer View, the Source View reflects that change. In the same way, when you turn off/on a flag in Source View, the Explorer View will identify that change and denote it accordingly.

## Visually Edit Jseopt.h Using Explorer View

The Explorer View displays the compiler options in a visual tree structure, structured in logical groups (Target Platform, Standard Libraries, Operating System Libraries, etc.). Each item in the tree represents an compiler option.

## Compiler Option Help

While in Explorer View, you can get further information for each of the flags by selecting it in the tree. When a node is selected, its #define flag and description is provided in the right pane. Additionally, general information for each of the categories is also provided in the description area.

### Tree Item Types

There are three main types of tree items: checkbox, radio button, and number value. These are described as follows:

#### *Checkbox*

 Windows

Check the checkbox to turn it on, uncheck to turn it off.

#### *Radio Button*

 Unicode

Select one of the radio options.

#### *Number*

 String hash table size

Click the push button to display a dialog box to modify the numeric define value.

## Changing Labels In Explorer View

You can toggle between Friendly Text and Flag Name labels inside of Explorer View. Friendly text provides a descriptive name for a #define flag being represented, while a flag name is the literal #define flag used in the source file. Use the appropriate menu item in View menu to toggle between these views. The default is Friendly Text.

## Manually Edit Jseopt.h Using Source View

If you prefer, you can also work with the jseopt.h file in Source View, which displays the actual source file. The Source View editor provides basic text editing capabilities (Cut, Copy, Paste, Undo, etc.) for use when modifying the jseopt.h file.

### Syntax Updating Rules

When modifying the jseopt.h file manually, avoid placing text comments in front the #define flag statement on the same line, in order to have the Selib Assistant function as expected. For example, the following two are valid:

```
/* The language extension library. */
```

```
#define JSE_LANG_ALL
```

or

```
/* The language extension library. */  
/* #define JSE_LANG_ALL */
```

However, the following are NOT valid:

```
/* The language extension library. */ #define JSE_LANG_ALL
```

or

```
/* The language extension library. */ /* #define JSE_LANG_ALL  
*/
```

## Basic Instructions for Working with a Jseopt.h File

- **Create New Jseopt.h.** Choose File | New or click the New toolbar button to create a new jseopt.h file with the default flags set.
- **Open Existing Jseopt.h.** Choose File | Open or click the Open toolbar button to open an existing jseopt.h on your file system.
- **Save Changes.** Choose File | Save or File | Save As to save changes.

## Build Libraries Mode

Build Libraries mode is used to build the ScriptEase library files (.lib) that your application will then utilize. The ScriptEase engine compiles into two libraries – one for the core ScriptEase interpreter and one for the ScriptEase extended libraries.

### Specifying A Character Set

Each ScriptEase library needs to be associated with a character set. The default is ASCII, but you can select from ASCII, MBCS, or Unicode. The character set is specified in the jseopt.h, which can be modified from the Set Options mode. When you enter Build Libraries mode, Selib Assistant will look for the current character set value in your jseopt.h file and display it in the Character Set radio group.

### Building Libraries

To build the libraries based on the active jseopt.h file, click the Build Now button. Selib Assistant will compile them using Visual Studio's command line utility. Debug and release versions of the core and extended libraries will be built.

The output files will be located in a win32\msvc60\static subdirectory under the location of the jseopt.h file. The results of the compilation process will be output

to the Results box in the Build Libraries view. (This information can also be found in the win32\msvc60\static\selib\_build.log file.)

The names of the .lib files created depend on the character set and built type:

Filename	ScriptEase Library	Charset	Build Type
sec501ar.lib	Core	Ascii	Release
sec501ad.lib	Core	Ascii	Debug
sec501mr.lib	Core	MBCS	Release
sec501md.lib	Core	MBCS	Debug
sec501ur.lib	Core	Unicode	Release
sec501ud.lib	Core	Unicode	Debug
sel501ar.lib	Extended	Ascii	Release
sel501ad.lib	Extended	Ascii	Debug
sel501mr.lib	Extended	MBCS	Release
sel501md.lib	Extended	MBCS	Debug
sel501ur.lib	Extended	Unicode	Release
sel501ud.lib	Extended	Unicode	Debug

In addition to the .lib files created, Selib Assistant will place Visual Studio project files (.dsp) for both libraries. The ScriptEase core library project is sec501.dsp, and the extended library project is sel501.dsp.

**Note:** The evaluation version of Selib Assistant has a prebuilt version of the core libraries that are copied to the win32\msvc60\static destination. Therefore, no .dsp file is available for the core library for the evaluation version.

## Add To Project Mode

Add To Project mode can be used to automatically link ScriptEase core and extended library files created in Build Libraries mode directly into your Visual Studio project. You will then be able to immediately start using ScriptEase functionality directly within your application.

To add to ScriptEase libraries to your project, following instructions below:

- The Recently built .lib files box will display the last set of .lib files generated by Selib Assistant. If this box is empty, be sure to use the Build Libraries mode first before continuing.
- In the Select build type to add box, choose either Debug or Release libraries to add to your project.

- In the Filename box, enter your Visual Studio project (.dsp file) that you would like to link the libraries to.
- If you'd also like to add the ScriptEase library .dsp files into your project's Workspace, then check the Add ScriptEase .dsp file(s) to Workspace option.
- Click the Add Now button.

Selib Assistant will link the .lib files into your project and optionally add their .dsp files to the Workspace.

# Appendices

- [Appendix 2: Using Wrapper.jse](#)
- [Appendix A: Grouped Functions](#)
- [Appendix B: Instance and Static Notation](#)

---

## Appendix 1: Standard Libraries

ScriptEase ships with a number of standard libraries which you can add to your application. The chapter "[Integration Into Your C/C++ Application](#)" describes how to do so, by modifying your `jseopt.h` file. Here is a list of the available libraries, the `#define` value you should define in your `jseopt.h` file to make a particular library available, and a short description of what the library contains.

### **BUFFER (#define JSE\_BUFFER\_ALL)**

The Buffer object provides a way to work with raw sequential data (e.g. read raw bytes, work with individual bytes, and read/write in formats such as FLOAT64, UWORD8, and so on).

### **CLIB (#define JSE\_CLIB\_ALL)**

A C-compatibility library. This library contains the complete set of C library functions in a ScriptEase form for use within scripts. They are all grouped under the `Clib` object, so there are functions such as `Clib.strcmp` and `Clib.fopen`.

### **CSTRING (#define JSE\_CSTRING\_ALL)**

The CString object provides an object that acts much like a string in the C language. Individual elements may be accessed with `str[index]` syntax, and pointer-like arithmetic is available (e.g. `index = str1 - str2`). The `Clib` object is aware of the CString object and will use it if available..

### **DOS (#define JSE\_DOS\_ALL)**

Useful DOS & Win16 functions. Grouped under the `SElib` object.

### **DSP (#define JSE\_DSP\_ALL)**

Nombas' Distributed Scripted Protocol for communicating between scripts. Most often used as a link library.

### **ECMA (#define JSE\_ECMA\_ALL)**

ECMA compatibility library. This is perhaps the most important library, as it provides the set of objects required by the ECMAScript specification. This includes the `String` object, `Math` object, `Date` object, and all other objects and methods required by the ECMA specification.

### **GD (#define JSE\_GD\_ALL)**

A GIF manipulation library based on the freely available `gd` package. Most often used as a link library.

### **IDSP (#define JSE\_IDSP\_ALL)**

The internet-enabled version of the DSP library. Most often used as a link library.

### **LANG (#define JSE\_LANG\_ALL)**

The language extension library. This contains common global functions such as `define` and `getArrayLength` which serve as general extensions to the JavaScript language.

## **MAC (#define JSE\_MAC\_ALL)**

Useful Macintosh functions. Grouped under the `SElib` object.

## **MD5 (#define JSE\_MD5\_ALL)**

An MD5 library, used for managing checksums. Most often used as link library.

## **NLM (#define JSE\_NLM\_ALL)**

Useful Netware functions.

## **OS2 (#define JSE\_OS2\_ALL)**

Useful OS2 functions. Grouped under `SElib` object.

## **SELIB (#define JSE\_SELIB\_ALL)**

A group of Nombas supplied functions which provide useful interfaces for some common tasks. They are grouped under the `SElib` object. Some functions include `SElib.directory` and `SElib.dynamicLink`.

## **SESOCKET (#define JSE\_SOCKET\_ALL)**

A socket library for Internet communications. Most often used as a link library.

## **TEST (#define JSE\_TEST\_ALL)**

A small suite of functions for testing scripts and the language. Grouped under the `Test` object.

## **UNIX (#define JSE\_UNIX\_ALL)**

Useful Unix functions. Grouped under the `SElib` object.

## **UUCODE (#define JSE\_UUCODE\_ALL)**

A library of UU Encoding and Decoding functions. Most often used as a link library.

## **WIN (#define JSE\_WIN\_ALL)**

Useful Windows 3.1/95/NT functions. Grouped under `SElib` object.

In addition to including the entire library, it is possible to include particular functions from the library or to exclude them. To include a particular function, do not define the `JSE_XXX_ALL`, but do define the particular function's `define` to 1. To exclude a function, do include all the functions in the library using the `JSE_XXX_ALL` `define`, but then define the particular function's `define` to 0. A list of the functions in each library and the `defines` to use them can be found in the file `tools\selibdef.dat`.

---

## Appendix 2: Using Wrapper.jse

The `wrapper.jse` script is a tool that generates ScriptEase wrapper functions to wrap C functions defined in a C header file. This is a quick and easy way to allow scripts to access your application's capabilities.

You need a C header that describes all of the functions you'd like to make wrappers for. You may have multiple headers and use `wrapper.jse` on each individually. Note that each header can include other headers, and those will not be wrapped. For instance, you may include `windows.h` to get needed defines, and `wrapper.jse` won't try to write wrappers for lots of Windows functions.

If your application relies on any `#defines` to properly parse its headers, you must provide a file with those defines in it and pass that filename as a parameter. Here is an example file of definitions you might need:

```
// mydefines.h:
#define WIN32 1
#define MY_APP_THINGEE 1
```

to tell `wrapper.jse` to use it, add the parameter

```
-defines mydefines.h
```

In addition, you need to pass the directories that contain the include files such as

```
-path c:\vc98\include -path c:\myapp\include
```

The only required parameter is your header file to translate. An example call would be:

```
secon32 wrapper.jse -defines mydefs.h -path c:\include example.h
```

The output for this example is the file `example_wrappers.c`, which you need to add to your application. Finally, you need to add the produced wrappers into your running context. You do this at the same time you add other wrapper libraries using `seAddLibTable`. Typically this is done in your `sePrepareContext` callback described in the [The seContextParams Structure](#). See the chapter on "[Wrapper functions](#)" for more information on wrapper functions and wrapper libraries. `wrapper.jse` generates a function for you to call at this point that adds its definitions. First, make sure to tell the compiler about the function by adding at the top of the file:

```
extern void example_add_wrappers(secontext se);
```

and add those wrapper library by calling:

```
example_add_wrappers(se);
```

Note that the name of the function to call and the `.c` file that implements it is dependent on the name of the header file it was produced from. In this case, `example.h` produces `example_wrappers.c` and `example_add_wrappers()`.

---

## Appendix A: Grouped Functions

In the current section, the functions and methods of ScriptEase are organized according to purpose and operation and not according to object. Some functions and methods are specific to certain operating systems and do not exist in all versions of ScriptEase. For example, `SELib.subclassWindow()` does not apply to the DOS operating system.

### Routines for arrays

#### For dynamic arrays

<code>Clib qsort()</code>	Sort an array.
<code>global.getLength()</code>	Determines size of an array.
<code>global.setLength()</code>	Sets the size of an array.

#### For Array objects

<code>Array concat()</code>	Concatenate to array.
<code>Array join()</code>	Creates a string from array elements.
<code>Array pop()</code>	Get last element of array.
<code>Array push()</code>	Add element to end of array.
<code>Array reverse()</code>	Reverses the order of elements of an array.
<code>Array shift()</code>	Get first element of array.
<code>Array slice()</code>	Get a subset of an array.
<code>Array sort()</code>	Sorts array elements.
<code>Array splice()</code>	Insert elements into array.
<code>Array unshift()</code>	Add elements to start of array.

#### Array properties

<code>Array length</code>	Returns the length of array.
---------------------------	------------------------------

`array.jsh` - arrays and objects

`item.jsh` - delimited strings/arrays

### Routines for Buffers

#### Buffer methods

<code>Buffer getString()</code>	Returns a string starting from the current cursor position.
<code>Buffer getValue()</code>	Returns a value from a specified position.
<code>Buffer putString()</code>	Puts a string into a buffer.
<code>Buffer putValue()</code>	Puts a specified value into a buffer.
<code>Buffer subBuffer()</code>	Returns a section of a buffer.
<code>Buffer toString()</code>	Returns string equivalent of the current state of buffer.

#### Buffer properties

<code>Buffer bigEndian</code>	Boolean flag for bigEndian byte ordering.
<code>Buffer cursor</code>	Current position within a buffer.
<code>Buffer size</code>	Size of a buffer object.

Buffer unicode

Boolean flag for the use of unicode strings.

## Routines for character classification

<code>Clib.isalnum()</code>	Tests for alphanumeric character.
<code>Clib.isalpha()</code>	Tests for alphabetic character.
<code>Clib.isascii()</code>	Tests for ASCII coded character.
<code>Clib.iscntrl()</code>	Tests for any control character.
<code>Clib.isdigit()</code>	Tests for any decimal-digit character.
<code>Clib.isgraph()</code>	Tests for any printing character except space.
<code>Clib.islower()</code>	Tests for lower-case alphabetic letter.
<code>Clib.isprint()</code>	Tests for any printing character.
<code>Clib.ispunct()</code>	Tests for punctuation character.
<code>Clib.isspace()</code>	Tests for white-space character.
<code>Clib.isupper()</code>	Tests for upper-case alphabetic character.
<code>Clib.isxdigit()</code>	Tests for hexadecimal-digit character.

## Routines for console I/O

<code>Clib.kbhit()</code>	Checks if a keyboard keystroke is available.
<code>Clib.getch()</code>	Gets a character from the keyboard, no echo.
<code>Clib.getchar()</code>	Gets character from standard input, keyboard.
<code>Clib.getche()</code>	Gets character from the keyboard, with echo.
<code>Clib.gets()</code>	Reads string from standard input, keyboard.
<code>Clib.perror()</code>	Displays a message describing error in <code>errno</code> .
<code>Clib.printf()</code>	Formatted output to standard output, screen.
<code>Clib.putchar()</code>	Writes a character to standard output, screen.
<code>Clib.puts()</code>	Writes a string to standard output, console.
<code>Clib.scanf()</code>	Formatted input from standard input, keyboard.
<code>Clib.vprintf()</code>	Formatted output to stdout, screen, variable args.
<code>Clib.vscanf()</code>	Formatted input from stdin, keyboard, variable args.

`dlgobj.jsh` - Dialog object

`getit.jsh` - `getItem` and `getLine`

`inout.jsh` - routines for input/output

`inputbox.jsh` - input box

`key.jsh` - keys and keyboard

`msgbox.jsh` - message boxes

## Routines for conversion/casting

<code>global.escape()</code>	Escapes special characters in a string.
<code>global.parseFloat()</code>	Converts a string to a Float.
<code>global.parseInt()</code>	Converts a string to an Integer.
<code>global.unescape()</code>	Removes escape sequences in a string.
<code>global.ToBoolean()</code>	Converts a value to a Boolean.
<code>global.ToBuffer()</code>	Converts a value to a buffer.
<code>global.ToBytes()</code>	Converts a value to a buffer, raw transfer.
<code>global.ToInt32()</code>	Converts a value to a large Integer.

<code>global.ToInteger()</code>	Converts a value to an Integer.
<code>global.ToNumber()</code>	Converts a value to a Number.
<code>global.ToObject()</code>	Converts a value to an Object.
<code>global.ToPrimitive()</code>	Converts a value to a Primitive.
<code>global.ToString()</code>	Converts a value to a String.
<code>global.ToUint16()</code>	Converts a value to an unsigned Integer.
<code>global.ToUint32()</code>	Converts a value to an unsigned large Integer.

`array.jsh` - arrays and objects

## Routines for data/variables

### Methods for data

<code>Blob get()</code>	Reads data from specified location of a Blob.
<code>Blob put()</code>	Writes data into specified location of a Blob.
<code>Blob size()</code>	Determine size of a Blob.
<code>blobDescriptor object</code>	Describe data in a Blob.

<code>global.defined()</code>	Tests if variable has been defined.
<code>global.getAttributes()</code>	Gets attributes of a variable.
<code>global.isFinite()</code>	Determines if a value is finite.
<code>global.isNaN()</code>	Determines if a value is Not a Number.
<code>global.setAttributes()</code>	Sets attributes of a variable.
<code>global.undefine()</code>	Makes a variable undefined.

`SElib.getObjectProperties()` Get name list of members of object/structure.

<code>toString()</code>	Converts any variable to a string representation.
<code>valueOf()</code>	Returns the value of any variable.

`profobj.jsh` - Profile object for ini files

`regobj.jsh` - Registry object

## Routines for date/time

<code>Clib.asctime()</code>	Converts data and time to an ASCII string.
<code>Clib.clock()</code>	Gets processor time.
<code>Clib.ctime()</code>	Converts date-time to an ASCII string.
<code>Clib.difftime()</code>	Computes difference between two times.
<code>Clib.gmtime()</code>	Converts data and time to GMT.
<code>Clib.localtime()</code>	Converts date/time to a structure.
<code>Clib.mktime()</code>	Converts time structure to calendar time.
<code>Clib.strftime()</code>	Formatted write of date/time to a string.
<code>Clib.time()</code>	Gets current time.

<code>Date getDate()</code>	Returns the day of the month.
<code>Date getDay()</code>	Returns the day of the week.
<code>Date getFullYear()</code>	Returns the year with four digits.
<code>Date getHours()</code>	Returns the hour.
<code>Date getMilliseconds()</code>	Returns the millisecond.

Date.getMinutes()	Returns the minute.
Date.getMonth()	Returns the month.
Date.getSeconds()	Returns the second.
Date.getTime()	Returns date/time, milliseconds, in Date object.
Date.getTimezoneOffset()	Returns difference, in minutes, from GMT.
Date.getUTCDate()	Returns the UTC day of the month.
Date.getUTCDay()	Returns the UTC day of the week.
Date.getUTCFullYear()	Returns the UTC year with four digits.
Date.getUTCHours()	Returns the UTC hour.
Date.getUTCMilliseconds()	Returns the UTC millisecond.
Date.getUTCMinutes()	Returns the UTC minute.
Date.getUTCMonth()	Returns the UTC month.
Date.getUTCSeconds()	Returns the UTC second.
Date.getYear()	Returns the year with two digits.
Date.setDate()	Set day of the month.
Date.setFullYear()	Sets the year with four digits.
Date.setHours()	Sets the hour.
Date.setMilliseconds()	Sets the millisecond.
Date.setMinutes()	Sets the minute.
Date.setMonth()	Sets the month.
Date.setSeconds()	Sets the second.
Date.setTime()	Sets date/time, in milliseconds, in Date object.
Date.setUTCDate()	Sets the UTC day of the month.
Date.setUTCFullYear()	Sets the UTC year with four digits.
Date.setUTCHours()	Sets the UTC hour.
Date.setUTCMilliseconds()	Sets the UTC millisecond.
Date.setUTCMinutes()	Sets the UTC minute.
Date.setUTCMonth()	Sets the UTC month.
Date.setUTCSeconds()	Sets the UTC second.
Date.setYear()	Sets the year with two digits.
Date.toString()	Returns the date portion of current date as string.
Date.toGMTString()	Converts a Date object to a string.
Date.toLocaleDateString()	Same as date.toString using local time.
Date.toLocaleString()	Returns a string for local date and time.
Date.toLocaleTimeString()	Same as date.toString using local time.
Date.toSystem()	Converts a Date object to a system time.
Date.toTimeString()	Returns the time portion of current date as string.
Date.toUTCString()	Returns a string that represents the UTC date.
Date.fromSystem()	Converts system time to Date object time.
Date.parse()	Converts a Date string to a Date object.
Date.UTC()	Returns date/time, milliseconds, use parameters.

datetime.jsh - date and time

## Routines for diagnostic/error

Clib.clearerr()	Clears end-of-file and error status for a file.
Clib.errno()	Returns value of error condition.
Clib.ferror()	Tests for error on a file stream.
Clib.perror()	Prints an message describing error in errno.

`Clib.sterror()` Gets a string describing an error number.

## **Routines for directory, file, and OS**

`Clib.chdir()` Changes directory.

`Clib.flock()` File locking.

`Clib.getcwd()` Gets current working directory.

`Clib.mkdir()` Makes a directory.

`Clib.rmdir()` Removes a directory.

`Clib.getenv()` Gets an environment string.

`Clib.putenv()` Sets an environment string.

`SElib.directory()` Searches directory listing for file spec.

`SElib.fullPath()` Converts partial path spec to full path name.

`SElib.splitFileName()` Gets directory, name, and extension parts of a file specification.

## Routines for DOS

Dos.address()	Set a memory address.
Dos.asm()	Execute machine code in a memory location.
Dos.inport()	Get byte from a hardware port.
Dos.inportw()	Get word from a hardware port.
Dos.interrupt()	Execute 8086 interrupt.
Dos.offset()	Get offset of memory address.
Dos.outport()	Write byte to hardware port.
Dos.outportw()	Write word to hardware port.
Dos.segment()	Get segment of memory address.

## Routines for execution control

Clib.abort()	Terminates program, normally due to error.
Clib.assert()	Test a condition and abort if it is <code>false</code> .
Clib.atexit()	Sets function to be called at program exit.
Clib.exit()	Normal program termination.
Clib.system()	Passes a command to the command processor.
global.eval()	Evaluate string as script code, like <code>SElib.interpret</code> .
SElib.baseWindowFunction()	Call base procedure for a window.
SElib.breakWindow()	Release control of a window.
SElib.compileScript()	Compiles script into executable code.
SElib.doWindows()	Start ScriptEase window manager.
SElib.dynamicLink()	Make a call to the API.
SElib.inSecurity()	Calls security manager initialization routine.
SElib.instance()	Get instance handle of currently executing script.
SElib.interpret()	Interprets ScriptEase code or source file.
SElib.interpretInNewThread()	Creates a new thread within a current process.
SElib.makeWindow()	Create window to be managed.
SElib.messageFilter()	Restrict messages to a window.
SElib.multiTask()	Toggle multitasking on and off.
SElib.ShellFilterCharacter()	Add character filter to ScriptEase shell.
SElib.ShellFilterCommand()	Add command filter to ScriptEase shell.
SElib.spawn()	Runs an external executable.
SElib.subclassWindow()	Hooks a windowFunction in message loop.
SElib.suspend()	Suspends program execution for a while.
SElib.windowList()	Get handles of child windows.

exec.jsh - execute programs  
getopt.jsh - get options  
keypush.jsh - keyboard simulation  
menuctrl.jsh - control menus  
message.jsh - for windows  
mouseclk.jsh - mouse simulation  
optparms.jsh - get parameters

winexec.jsh - execute programs

## Routines for file/stream I/O

<code>Clib.fclose()</code>	Closes an open file.
<code>Clib.feof()</code>	Tests if at end of file stream.
<code>Clib fflush()</code>	Flushes stream for open file(s).
<code>Clib.fgetc()</code>	Gets a character from file stream.
<code>Clib.fgetpos()</code>	Gets current position of a file stream.
<code>Clib.fgets()</code>	Gets a string from an input stream.
<code>Clib fopen()</code>	Opens a file.
<code>Clib fprintf()</code>	Formatted output to a file stream.
<code>Clib.fputc()</code>	Writes a character to a file stream.
<code>Clib fputs()</code>	Writes a string to a file stream.
<code>Clib fread()</code>	Reads data from a file.
<code>Clib freopen()</code>	Assigns new file spec to a file handle.
<code>Clib fscanff()</code>	Formatted input from a file stream.
<code>Clib fseek()</code>	Sets file position for an open file stream.
<code>Clib.fsetpos()</code>	Sets position of a file stream.
<code>Clib.ftell()</code>	Gets the current value of the file position.
<code>Clib.fwrite()</code>	Writes data to a file.
<code>Clib.getc()</code>	Gets a character from file stream.
<code>Clib.putc()</code>	Writes a character to a file stream.
<code>Clib.remove()</code>	Deletes a file.
<code>Clib.rename()</code>	Renames a file.
<code>Clib.rewind()</code>	Resets file position to beginning of file.
<code>Clib.tmpfile()</code>	Creates a temporary binary file.
<code>Clib.tmpnam()</code>	Gets a temporary file name.
<code>Clib.ungetc()</code>	Pushes character back to input stream.
<code>Clib.vfprintf()</code>	Formatted output to a file stream using variable args.
<code>Clib.vscanff()</code>	Formatted input from a file stream using variable args.

copyfile.jsh - copying files

fileobj.jsh - File objects

## Routines for general use

profobj.jsh - Profile object for ini files

regobj.jsh - Registry object

seutil.jsh - ScriptEase header

## Routines for math

### Math methods

<code>Clib.abs()</code>	Returns the absolute value of an integer.
<code>Clib.acos()</code>	Calculates the arc cosine.
<code>Clib.asin()</code>	Calculates the arc sine.
<code>Clib.atan()</code>	Calculates the arc tangent.
<code>Clib.atan2()</code>	Calculates the arc tangent of a fraction.
<code>Clib.atof()</code>	Converts ASCII string to a floating-point number.

<code>Clib.atoi()</code>	Converts ASCII string to an integer.
<code>Clib.atol()</code>	Converts ASCII string to an integer.
<code>Clib.ceil()</code>	Rounds up.
<code>Clib.cos()</code>	Calculates the cosine.
<code>Clib.cosh()</code>	Calculates the hyperbolic cosine.
<code>Clib.div()</code>	Integer division, returns quotient & remainder.
<code>Clib.exp()</code>	Computes the exponential function.
<code>Clib.fabs()</code>	Absolute value.
<code>Clib.floor()</code>	Rounds down.
<code>Clib.fmod()</code>	Modulus, calculate remainder.
<code>Clib.frexp()</code>	Breaks into a mantissa and an exponential power of 2.
<code>Clib.labs()</code>	Returns the absolute value of an integer.
<code>Clib.ldexp()</code>	Calculates mantissa * 2 ^ exp.
<code>Clib.ldiv()</code>	Integer division, returns quotient & remainder.
<code>Clib.log()</code>	Calculates the natural logarithm.
<code>Clib.log10()</code>	Calculates the base-ten logarithm.
<code>Clib.max()</code>	Returns the largest of one or more values.
<code>Clib.min()</code>	Returns the minimum of one or more values.
<code>Clib.modf()</code>	Splits a value into integer and fractional parts.
<code>Clib.pow()</code>	Calculates x to the power of y.
<code>Clib.rand()</code>	Generates a random number.
<code>Clib.sin()</code>	Calculates the sine.
<code>Clib.sinh()</code>	Calculates the hyperbolic sine.
<code>Clib.sqrt()</code>	Calculates the square root.
<code>Clib.srand()</code>	Seeds random number generator.
<code>Clib.tan()</code>	Calculates the tangent.
<code>Clib.tanh()</code>	Calculates the hyperbolic tangent.

<code>Math.abs()</code>	Returns the absolute value of an integer.
<code>Math.acos()</code>	Calculates the arc cosine.
<code>Math.asin()</code>	Calculates the arc sine.
<code>Math.atan()</code>	Calculates the arc tangent.
<code>Math.atan2()</code>	Calculates the arc tangent of a fraction.
<code>Math.ceil()</code>	Rounds up.
<code>Math.cos()</code>	Calculates the cosine.
<code>Math.exp()</code>	Computes the exponential function.
<code>Math.floor()</code>	Rounds down.
<code>Math.log()</code>	Calculates the natural logarithm.
<code>Math.max()</code>	Returns the largest of one or more values.
<code>Math.min()</code>	Returns the minimum of one or more values.
<code>Math.pow()</code>	Calculates x to the power of y.
<code>Math.random()</code>	Returns a random number.
<code>Math.round()</code>	Rounds value up or down.
<code>Math.sin()</code>	Calculates the sine.
<code>Math.sqrt()</code>	Calculates the square root.
<code>Math.tan()</code>	Calculates the tangent.

## Math properties

<code>Math.E</code>	Value of e, base for natural logarithms.
<code>Math.LN10</code>	Value for the natural logarithm of 10.

Math.LN2	Value for the natural logarithm of 2.
Math.LOG2E	Value for the base 2 logarithm of e.
Math.LOG10E	Value for the base 10 logarithm of e.
Math.PI	Value for pi.
Math.SQRT1_2	Value for the square root of 2.
Math.SQRT2	Value for the square root of 2.
Number.MAX_VALUE	Largest number (positive)
Number.MIN_VALUE	Smallest number (negative)
Number.NaN	Not a Number
Number.NEGATIVE_INFINITY	Number below MIN_VALUE
Number.POSITIVE_INFINITY	Number above MAX_VALUE

## Routines for memory manipulation

Clib.bsearch()	Binary search in memory/array/buffer.
SElib.peek()	Reads data from memory location.
SElib.pointer()	Gets address of variable.
SElib.poke()	Writes data to memory location.

## Routines for miscellaneous

Clib.bsearch()	Binary search for member of a sorted array.
Clib.qsort()	Sorts an array, may use comparison function.

## Routines for objects and functions

SElib.getObjectProperties()	Get names of properties of an object.
Object hasOwnProperty()	Determine if an object has a property.
Object isPrototypeOf()	Determine if a property is part of prototype.
Object	Is the attribute of a property DONT_ENUM.
propertyIsEnumerable()	
Object toLocaleString()	Object to string using local settings.

array.jsh - arrays and objects

Function apply()	Apply arguments array to a function.
Function call()	Call function with argument list.

## Routines for regular expressions

RegExp compile()	Sets a regular expression for the object.
RegExp exec()	Performs regular expression search.
RegExp test()	Tests a regular expression search.
String match()	Regular expression match
String replace()	Regular expression search/replace
String search()	Regular expression search

## Routines for strings/byte arrays

### Methods for strings

<code>Clib.memchr()</code>	Searches a byte array.
<code>Clib.memcmp()</code>	Compares two byte arrays.
<code>Clib.memcpy()</code>	Copies from one byte array to another.
<code>Clib.memmove()</code>	Moves from one byte array to another.
<code>Clib.memset()</code>	Copies character to byte array.
<code>Clib.rsprintf()</code>	Returns formatted string.
<code>Clib.sprintf()</code>	Formatted output to a string.
<code>Clib.sscanf()</code>	Formatted input from a string.
<code>Clib.strcat()</code>	Concatenates strings.
<code>Clib strchr()</code>	Searches a string for a character.
<code>Clib strcmp()</code>	Compares two strings.
<code>Clib strcmpi()</code>	Case-insensitive compare of two strings.
<code>Clib strcpy()</code>	Copies one string to another.
<code>Clib strcspn()</code>	Searches string for first character in a set of characters.
<code>Clib stricmp()</code>	Case-insensitive compare of two strings.
<code>Clib strlen()</code>	Gets the length of a string.
<code>Clib strlwr()</code>	Converts a string to lowercase.
<code>Clib strncat()</code>	Concatenates bytes of one string to another.
<code>Clib strncmp()</code>	Compares part of two strings.
<code>Clib strncmpi()</code>	Case-insensitive compare of parts of two strings.
<code>Clib strncpy()</code>	Copies bytes from one string to another.
<code>Clib strnicmp()</code>	Case-insensitive compare of parts of two strings.
<code>Clib strpbrk()</code>	Searches string for character from a set of characters.
<code>Clib strrchr()</code>	Searches string for the last occurrence of a character.
<code>Clib strspn()</code>	Searches string for character not in a set of characters.
<code>Clib strstr()</code>	Searches a string for a substring.
<code>Clib strstri()</code>	Case insensitive version of <code>Clib strstr</code> .
<code>Clib strtod()</code>	Converts a string to a floating-point value.
<code>Clib strtok()</code>	Searches a string for delimited tokens.
<code>Clib strtol()</code>	Converts a string to an integer value.
<code>Clibstrupr()</code>	Converts a string to uppercase.
<code>Clib.toascii()</code>	Converts to ASCII.
<code>Clib.tolower()</code>	Converts to lowercase.
<code>Clib.toupper()</code>	Converts to uppercase.
<code>Clib.vsprintf()</code>	Formatted output to string using variable args.
<code>Clib.vsscanf()</code>	Formatted input from a string.
<code>String.charAt()</code>	Returns a character in a string.
<code>String.charCodeAtAt()</code>	Returns a unicode character in a string.
<code>String.concat()</code>	Concatenate a string.
<code>String.indexOf()</code>	Returns index of first substring in a string.
<code>String.lastIndexOf()</code>	Returns index of last substring in a string.
<code>String.localeCompare()</code>	Compare string using local settings.
<code>String.slice()</code>	Get a substring from a string.
<code>String.split()</code>	Splits a string into an array of strings.

<code>String.substring()</code>	Retrieves a section of a string.
<code>String.toLocaleLowerCase()</code>	Returns lowercase string using local settings.
<code>String.toLocaleUpperCase()</code>	Returns uppercase string using local settings.
<code>String.toLowerCase()</code>	Converts a string to lowercase.
<code>String.toUpperCase()</code>	Converts a string to uppercase.

`String.fromCharCode()` Creates a string from character codes.

item.jsh - delimited strings/arrays

string.jsh - more for strings

## String properties

`String.length` Holds the length of a string in characters.

## Routines for variable argument lists

<code>Clib.va_arg()</code>	Retrieves variable from variable list of args.
<code>Clib.va_end()</code>	Terminates variable list of args.
<code>Clib.va_start()</code>	Starts a variable list of args.
<code>Clib.rvsprintf()</code>	Returns formatted string using variable args.
<code>Clib.vfprintf()</code>	Formatted output to a file stream using variable args.
<code>Clib.vfscanf()</code>	Formatted input from file stream using variable args.
<code>Clib.vprintf()</code>	Formatted output to stdout, screen, using variable args.
<code>Clib.vscanf()</code>	Formatted input from stdin, using var args.
<code>Clib.vsprintf()</code>	Formatted output to string using variable args.
<code>Clib.vsscanf()</code>	Formatted input from a string.

## Routines for UNIX

<code>Unix.fork()</code>	Create duplicate processes.
<code>Unix.kill()</code>	Wrapper for UNIX kill command.
<code>Unix.setgid()</code>	Change group id.
<code>Unix.setsid()</code>	Create a new session.
<code>Unix.setuid()</code>	Change user id.
<code>Unix.wait()</code>	Suspend execution until child process stops.
<code>Unix.waitpid()</code>	Suspend execution with additional controls.

---

## Appendix B: Instance and Static Notation

ScriptEase uses object properties which are integral to JavaScript. For clarity we refer to object **properties** and object **methods**, not just properties, though both properties and methods may be referred to by the general term property. When using the terms property and method, object properties refer to the variables and data of an object and object methods refer to the functions of an object. We have clarified one dimension of object properties and methods. But, to be precise, we must deal with another dimension.

Object properties and methods are either **instance**, belonging to an instance of an object, or **static**, belonging to an object itself. Thus, all properties and methods of an object may be classified according to two dimensions. Is a property of an object a property or a method, and is it an instance or a static property? The following examples illustrate

- Instance property `string.length`
- Instance method `string.indexOf()`
- Static property `String.illus`
- Static method `String.fromCharCode()`

Objects may have all four categories of methods and properties, but usually they do not. In this illustration, the `String` object has three of the categories, but not a static property, which is the reason why `String.illus` had to be made up for this example.

ScriptEase documentation uses a couple of style conventions to distinguish between properties and methods and between being instance or static. The four sections, following the bullet list of explanations, illustrate how these distinctions are made in reference sections of documentation.

- First, headings, such as "String instance properties" below, specifically identify whether the following reference information applies to instance properties, instance methods, static properties, or static methods.
- Second, properties do not have parentheses "()" but methods do.
- Third the top lines of reference tables vary in how they refer to instance and static properties and methods. Instance properties and methods have object names followed by a space, such as "String ", whereas static properties and methods have object names followed by a period, such as "String."
- Fourth, the syntax line for instance properties and methods uses the object name in all lowercase, whereas, the syntax line for static properties and methods uses the object name precisely. The significance is that instance properties and methods actually use the variable name of an instance of an object, whereas, static properties and methods use the actual object name itself.
- Fifth, the use of lowercase for instance properties and methods is used consistently in text and descriptions, not just the reference tables themselves.

### String instance properties sample

## String length

---

SYNTAX: `string.length`

DESCRIPTION:

SEE:

EXAMPLE:

---

## String instance methods sample

### String indexOf

---

SYNTAX: `string.indexOf(substring[, offset])`

WHERE:

RETURN:

DESCRIPTION:

EXAMPLE:

---

## String static methods sample

### String.fromCharCode()

---

SYNTAX: `String.fromCharCode(char1[, char2 ...])`

WHERE:

RETURN:

DESCRIPTION:

SEE:

EXAMPLE:

---

## Prototype property

For the technically inclined, objects have a `prototype` property. Instance properties and methods are attached to the `prototype` property of an object. As an illustration, assume that two new methods and two new properties are added to the `String` object. The instance property and method are added to the `prototype` property of the `String` object, whereas, the static property and method are added to the `String` object itself.

The following two declaration lines illustrate an instance property and an instance method:

```
String.prototype.newInstanceProperty  
String.prototype.newInstanceMethod()
```

The following two declaration lines illustrate a static property and a static method:

```
String.newStaticProperty  
String.newStaticMethod()
```

The following code fragment illustrates the differences in using these properties and methods.

```
    // Begin an instance of a String object  
var newStr = "an example string";  
var instVal = newStr.newInstanceProperty;  
newStr.newInstanceMethod();  
    // Use the static property and method directly  
var statVal = String.newStaticProperty;  
String.newStaticMethod();
```
